### **ABSTRACT**

This paper develops a quantitative model of internal city structure that features agglomeration and dispersion forces and an arbitrary number of heterogeneous city blocks. The model remains tractable and amenable to empirical analysis because of stochastic shocks to commuting decisions, which yield a gravity equation for commuting flows. To structurally estimate agglomeration and dispersion forces, we use data on thousands of city blocks in Berlin for 1936, 1986 and 2006 and exogenous variation from the city's division and reunification. We estimate substantial and highly localized production and residential externalities. We show that the model with the estimated agglomeration parameters can account both qualitatively and quantitatively for the observed changes in city structure.

# 1 Introduction

Economic activity is highly unevenly distributed across space, as reflected in the existence of cities and the concentration of economic functions in specific locations within cities, such as Manhattan in New York and the Square Mile in London. Understanding the strength of the agglomeration and dispersion forces that underlie these concentrations of economic activity is central to a range of economic and policy questions. These forces shape the size and internal structure of cities, with implications for the incomes of immobile factors, congestion costs and city productivity. They also determine the impact of public policy interventions, such as transport infrastructure investments and urban development and taxation policies.

Although there is a long literature on economic geography and urban economics dating back to at least [Marshall \(1920\)](#), a central challenge remains distinguishing agglomeration and dispersion forces from variation in locational fundamentals. While high land prices and levels of economic activity in a group of neighboring locations are consistent with strong agglomeration forces, they are also consistent with shared amenities that make these locations attractive places to live (e.g. leafy streets and scenic views) or common natural advantages that make these locations attractive for production (e.g. access to natural water). This challenge has both theoretical and empirical dimensions. From a theoretical perspective, to develop tractable models of cities, the existing literature typically makes simplifying assumptions such as monocentricity or symmetry, which abstracts from variation in locational fundamentals and limits the usefulness of these models for empirical work. From an empirical perspective, the challenge is to find exogenous sources of variation in the surrounding concentration of economic activity to help disentangle agglomeration and dispersion forces from variation in locational fundamentals.

In this paper, we develop a quantitative theoretical model of internal city structure. This model incorporates agglomeration and dispersion forces and an arbitrary number of heterogeneous locations within the city, while remaining tractable and amenable to empirical analysis. Locations differ in terms of their productivity, their amenities, their density of development (the ratio of floor area to ground area), and their access to transport infrastructure. Productivity depends on production externalities, which are increasing in the surrounding density of employment, and production fundamentals, such as topography and proximity to natural supplies of water. Amenities depend on residential externalities, which are increasing in the surrounding density of residents, and residential fundamentals, such as access to forests and lakes. Congestion forces take the form of an inelastic supply of land and commuting costs that are increasing in travel time, where travel time in turn depends on the transport network.<sup>1</sup>

We combine this quantitative theoretical model with the natural experiment of Berlin’s division in the aftermath of the Second World War and its reunification following the fall of the Iron Curtain. The division of Berlin severed all local economic interactions between East and West Berlin, which corresponds in the model to prohibitive trade and commuting costs and no production and residential externalities between these two parts of the city. We make use of a remarkable and newly-collected dataset for Berlin, which in-

---

<sup>1</sup>We use “production fundamental” to refer to a characteristic of a location that directly affects productivity (e.g. natural water) independently of the surrounding economic activity. We use “residential fundamental” to refer to a characteristic of a location that directly affects the utility of residents (e.g. forests) independently of the surrounding economic activity.

cludes data on land prices, employment by workplace and employment by residence covering the pre-war, division and reunification periods. Before structurally estimating the model, we first present reduced-form evidence showing that division leads to a reorientation of the gradient in land prices and employment in West Berlin away from the main pre-war concentration of economic activity in East Berlin, while reunification leads to a reemergence of this gradient. In contrast, there is little effect of division or reunification on land prices or employment along other more economically remote sections of the Berlin Wall. We show that these results are not driven by pre-trends prior to division or reunification. We also show that these results are robust to controlling for a host of observable block characteristics, including controls for access to the transport network, schools, parks and other green areas, lakes and other water areas, Second World War destruction, land use, urban regeneration policies and government buildings post reunification.

Having provided evidence in support of the model's qualitative predictions, we next examine whether it can account quantitatively for the observed impact of division and reunification. We begin by using the model's gravity equation predictions for commuting flows to determine its commuting parameters. Given this subset of the model's parameters, we show how profit maximization and zero profits, utility maximization and population mobility and land market clearing can be used to solve for overall measures of productivity, amenities and the density of development regardless of the relative contributions of externalities and fundamentals. In the special case of the model in which productivity and amenities are exogenous, the model has a unique equilibrium, and hence can be used to undertake counterfactuals that have determinate predictions for the impact of division and reunification. We use these counterfactuals to show that the model with exogenous productivity and amenities is unable to account quantitatively for observed impact of division and reunification on the pattern of economic activity within West Berlin.

We next use the exogenous variation from Berlin's division and reunification to structurally estimate both the model's commuting and agglomeration parameters. We decompose productivity and amenities into production and residential externalities (which capture agglomeration forces) and production and residential fundamentals (which are structural residuals that are one-to-one functions of the observed data and the parameters). Our identifying assumption is that changes in these structural residuals are uncorrelated with the exogenous change in the surrounding concentration of economic activity induced by Berlin's division and reunification. This identifying assumption requires that the systematic change in the pattern of economic activity in West Berlin following division and reunification is explained by the mechanisms in the model (the changes in commuting access and production and residential externalities) rather than by systematic changes in the pattern of structural residuals (production and residential fundamentals).

Our structural estimates of the model's parameters imply substantial and highly localized production externalities. Our estimated elasticity of productivity with respect to the density of workplace employment for division is 0.07, which is towards the high end of the range of existing estimates using variation between cities. In contrast to these existing estimates using data across cities, our analysis makes use of variation within cities. Our structural estimate of the elasticity of productivity with respect to density holds constant the distribution of travel times within the city. In reality, a doubling in total city population is typically achieved by a combination of an increase in the density of economic activity and an expansion in

geographical land area, which increases travel times within the city. Since production externalities decay rapidly with travel times, this attenuates production externalities, which has to be taken into account when comparing estimates within and across cities. We also find substantial and highly localized residential externalities. Our estimated elasticity of amenities with respect to the density of residence employment for division is 0.14, which is consistent with the view that consumption externalities are an important agglomeration force in addition to production externalities.

In the presence of agglomeration forces, there is potential for multiple equilibria in the model. An advantage of our estimation approach is that it addresses the potential existence of multiple equilibria. We distinguish between calibrating the model to the observed data given known parameter values and estimating the model for unknown parameters. First, given known values for the model parameters, we show formally that there is a unique mapping from these parameters and the observed data to the structural residuals (production and residential fundamentals). This mapping is unique irrespective of whether the model has a unique equilibrium or multiple equilibria. Second, when we estimate the model's parameters, we use the result that the structural residuals are one-to-one functions of the observed data and the model parameters to construct moment conditions in terms of these structural residuals. In principle, these moment conditions need not uniquely identify the model parameters, because the objective function defined by them need not be globally concave. For example, there could be multiple local minima corresponding to different equilibria of the model with different parameter values. In practice, we find that the objective function is well behaved in the parameter space, and that these moment conditions determine a unique value for the parameter vector.

When we undertake counterfactuals for the impact of division or reunification in the estimated model with agglomeration forces, we solve for the counterfactual equilibrium using the initial values from the observed equilibrium prior to division or reunification. Therefore we assume the equilibrium selection rule of searching for the counterfactual equilibrium closest to the observed equilibrium prior to division or reunification. Our goal in these counterfactuals is not to uniquely determine the effects of division or reunification, but rather to show that the model is capable of generating counterfactual predictions for the treatment effect of division or reunification that are close to the observed treatment effect.

Finally, we undertake a variety of over identification checks and robustness tests. First, estimating the model's commuting parameters using data on bilateral commuting flows for 2008, we show that the model is successful in capturing the cumulative distribution of commuters across travel times in the pre-war, division and reunification periods. Second, we find that the density of development in the model is strongly related to separate data on the ratio of floor space to geographical land area not used in the estimation of the model. Finally, we also find that production and residential fundamentals in the model are correlated in the expected way with observable proxies for these fundamentals.

Our paper builds on the large theoretical literature on urban economies. Much of this literature has analyzed the monocentric city model, in which firms are assumed to locate in a Central Business District (CBD) and workers decide how close to live to this CBD.<sup>2</sup> [Lucas and Rossi-Hansberg \(2002\)](#) were the first

---

<sup>2</sup>The classic urban models of [Alonso \(1964\)](#), [Mills \(1967\)](#) and [Muth \(1969\)](#) assume monocentricity. While [Fujita and Ogawa](#)

to develop a model of a two-dimensional city, in which equilibrium patterns of economic activity can be non-monocentric. In their model, space is continuous and the city is assumed to be symmetric, so that distance from the center is a summary statistic for the organization of economic activity within the city.<sup>3</sup> Empirically cities are, however, not perfectly symmetric because of variation in locational fundamentals, and most data on cities are reported for discrete spatial units such as blocks or census tracts.

Our contribution is to develop a quantitative theoretical model of internal city structure that allows for a large number of discrete locations within the city that can differ arbitrarily in terms of their natural advantages for production, residential amenities, land supply and transport infrastructure. The analysis remains tractable despite the large number of asymmetric locations because we incorporate a stochastic formulation of workers' commuting decisions that follows [Eaton and Kortum \(2002\)](#) and [McFadden \(1974\)](#). This stochastic formulation yields a system of equations that can be solved for unique equilibrium wages given observed workplace and residence employment in each location. It also provides microeconomic foundations for a gravity equation for commuting flows that has been found to be empirically successful.<sup>4</sup>

Our paper is also related to the broader literature on the nature and sources of agglomeration economies, as reviewed in [Duranton and Puga \(2004\)](#) and [Rosenthal and Strange \(2004\)](#). A large empirical literature has regressed wages, land prices, productivity or employment growth on population density.<sup>5</sup> We contribute to the small strand of research within this literature that has sought sources of exogenous variation in the surrounding concentration of economic activity. For example, [Rosenthal and Strange \(2008\)](#) and [Combes, Duranton, Gobillon, and Roux \(2010\)](#) use geology as an instrument for population density, exploiting the idea that tall buildings are easier to construct where solid bedrock is accessible. [Greenstone, Hornbeck, and Moretti \(2010\)](#) provide evidence on agglomeration spillovers by comparing changes in total factor productivity (TFP) among incumbent plants in "winning" counties that attracted a large manufacturing plant and "losing" counties that were the new plants runner-up choice.<sup>6</sup>

Other related research has examined the effect of historical natural experiments on the location of economic activity, including [Hanson \(1996, 1997\)](#) using Mexican trade liberalization; [Davis and Weinstein \(2002, 2008\)](#) using the wartime bombing of Japan; [Bleakley and Lin \(2012\)](#) using historical portage sites; and [Kline and Moretti \(2014\)](#) using the Tennessee Valley Authority (TVA). Using the division and reunification of Germany, [Redding and Sturm \(2008\)](#) examine the effect of changes in market access on the growth of West German cities, and [Redding, Sturm, and Wolf \(2011\)](#) examine the relocation of Germany's air hub from Berlin to Frankfurt as a shift between multiple steady-states. In contrast to all of the above studies, which exploit variation across regions or cities, our focus is on the determinants of economic activity within cities.<sup>7</sup>

---

(1982) and [Fujita and Krugman \(1995\)](#) allow for non-monocentricity, they model one-dimensional cities on the real line.

<sup>3</sup>For an empirical analysis of the symmetric-city model of [Lucas and Rossi-Hansberg \(2002\)](#), see [Brinkman \(2013\)](#).

<sup>4</sup>See [Grogger and Hanson \(2011\)](#) and [Kennan and Walker \(2011\)](#) for analyses of worker migration decisions using stochastic formulations of utility following [McFadden \(1974\)](#).

<sup>5</sup>See, for example, [Ciccone and Hall \(1996\)](#), [Dekle and Eaton \(1999\)](#), [Glaeser and Mare \(2001\)](#), [Henderson, Ari, and Turner \(1995\)](#), [Moretti \(2004\)](#), [Rauch \(1993\)](#), [Roback \(1982\)](#) and [Sveikauskas \(1975\)](#), as surveyed in [Moretti \(2011\)](#).

<sup>6</sup>Another related empirical literature has examined the relationship between economic activity and transport infrastructure, including [Donaldson \(2014\)](#), [Baum-Snow \(2007\)](#), [Duranton and Turner \(2012\)](#), [Faber \(2014\)](#) and [Michaels \(2008\)](#).

<sup>7</sup>Other research using within-city data includes [Arzaghi and Henderson \(2008\)](#) on the location of advertising agencies in Manhattan and [Rossi-Hansberg, Sarte, and Owens \(2010\)](#) on urban revitalization policies in Richmond, Virginia.

Our main contribution is to develop a tractable quantitative model of internal city structure that incorporates agglomeration forces and a rich geography of heterogeneous location characteristics and structurally estimate the model using the exogenous variation of Berlin's division and reunification.

The remainder of the paper is structured as follows. Section 2 discusses the historical background. Section 3 outlines the model. Section 4 introduces our data. Section 5 presents reduced-form empirical results on the impact of Berlin's division and reunification. Section 6 uses the model's gravity equation predictions to determine the commuting parameters, productivity, amenities and the density of development. Section 7 estimates the model's commuting and agglomeration parameters and separates productivity and amenities into externalities and fundamentals. Section 8 concludes.

## 2 Historical Background

The city of Berlin in its current boundaries was created in 1920 when the historical city and its surrounding agglomeration were incorporated under the Greater Berlin law ("Gross Berlin Gesetz"). The city comprises 892 square kilometers of land compared to 606 square kilometers for Chicago. The city was originally divided into 20 districts ("Bezirke"), which had minimal administrative autonomy.<sup>8</sup> The political process that ultimately led to the construction of the Berlin Wall had its origins in war-time planning during the Second World War. A protocol signed in London in September 1944 delineated zones of occupation in Germany for the American, British and Soviet armies after the eventual defeat of Germany. This protocol also stipulated that Berlin, although around 200 kilometers within the Soviet occupation zone, should be jointly occupied. For this purpose, Berlin was itself divided into separate occupation sectors.

The key principles underlying the drawing of the boundaries of the occupation sectors in Berlin were that the sectors should be geographically orientated to correspond with the occupation zones (with the Soviets in the East and the Western Allies in the West); the boundaries between them should respect the boundaries of the existing administrative districts of Berlin; and the American, British and Soviet sectors should be approximately equal in population (prior to the creation of the French sector from part of the British sector). The final agreement in July 1945 allocated six districts to the American sector (31 percent of the 1939 population and 24 percent of the area), four districts to the British sector (21 percent of the 1939 population and 19 percent of the area), two districts to the French sector (12 percent of the 1939 population and 12 percent of the area), and eight districts to the Soviet sector (37 percent of the 1939 population and 46 percent of the area).<sup>9</sup>

The London protocol specifying the occupation sectors also created institutions for a joint administration of Berlin (and Germany more generally). The intention was for Berlin to be governed as a single economic and administrative unit by a joint council ("Kommandatura") with Soviet, American, British and

---

<sup>8</sup>The boundaries of these 20 districts were slightly revised in April 1938. During division, the East Berlin authorities created three new districts (Hellersdorf, Marzahn and Hohenschönhausen), which were sub-divisions of Weissensee and Lichtenberg. Except for a few other minor changes, as discussed in [Elkins and Hofmeister \(1988\)](#), the district boundaries remained unchanged during the post-war period until an administrative reform in 2001, which reduced the overall number of districts to twelve.

<sup>9</sup>The occupation sectors were based on the April 1938 revision of the boundaries of the 20 pre-war districts. For further discussion of the diplomatic history of the division of Berlin, see [Franklin \(1963\)](#) and [Sharp \(1975\)](#).

French representatives. However, with the onset of the Cold War, the relationship between the Western allies and the Soviet Union began to deteriorate. In June 1948 the Western allies unilaterally introduced a new currency in their occupation zones and the Western sectors of Berlin. In retaliation the Soviet Union decided to block all road and rail access to the Western sectors of Berlin for nearly eleven months and West Berlin was supplied through the Berlin airlift during this time. The foundation of East and West Germany as separate states in 1949 and the creation of separate city governments in East and West Berlin further cemented the division of Germany and Berlin into Eastern and Western parts.

Following the adoption of Soviet-style policies of command and control in East Germany, the main border between East and West Germany was closed in 1952. While the implementation of these policies in East Berlin limited economic interactions with the Western sectors, the boundary between East and West Berlin remained formally open.<sup>10</sup> This open border resulted in some commuting of workers between East and West Berlin.<sup>11</sup> It also became a conduit for refugees fleeing to West Germany. To stem this flow of refugees, the East German authorities constructed the Berlin Wall in 1961, which ended all local economic interactions between East and West Berlin.

As shown in Figure 1, the Berlin Wall consisted of an inner boundary between West and East Berlin and an outer boundary between West Berlin and East Germany. The inner boundary ran along the Western edge of the district Mitte, which contained the pre-war CBD. As a result, West Berlin was separated from the pre-war commercial heart of the city, which contained Berlin's main administrative, cultural and educational institutions and by far the largest pre-war concentration of employment. The Berlin Wall cut through the pre-war transport network, intersecting underground railway ("U-Bahn") and suburban railway ("S-Bahn") lines, which were closed off at the boundaries with East Berlin or East Germany.<sup>12</sup> During the period of division, West Germany introduced a number of policies to support economic activity in West Berlin, such as subsidies to transportation between West Berlin and West Germany, reduced tax rates and an exemption from military service for residents of West Berlin. Whereas our empirical analysis exploits relative variation across locations within West Berlin, these policies applied equally to all of Berlin.

While the division of Germany and Berlin appeared to be permanent, the Soviet policies of "Glasnost" and "Perestroika" introduced by Mikhail Gorbachev in 1985 started a process of opening up of Eastern Europe.<sup>13</sup> As part of this wider transformation, large-scale demonstrations in East Germany in 1989 led to the fall of the Berlin Wall on 9 November 1989. In the aftermath of these events, the East German system

---

<sup>10</sup>While East Berlin remained the main concentration of economic activity in East Germany after division, only around 2 percent of West Berlin's exports from 1957-1967 were to East Germany (including East Berlin) and other Eastern block countries (see [Lambrecht and Tischner 1969](#)).

<sup>11</sup>Approximately 122,000 people commuted from West to East Berlin in the fall of 1949, but this number quickly declines after waves of mass redundancies of Western workers in East Berlin and stands at about 13,000 workers in 1961 just before the construction of the Berlin Wall. Commuting flows in the opposite direction are estimated to be 76,000 in 1949 and decline to 31,000 in 1953 before slowly climbing to 63,000 in 1961 ([Roggenbuch 2008](#)).

<sup>12</sup>In a few cases, trains briefly passed through East Berlin territory en route from one part of West Berlin to another. These cases gave rise to ghost stations ("Geisterbahnhöfe") in East Berlin, where trains passed through stations patrolled by East German guards without stopping.

<sup>13</sup>After the signing of the Basic Treaty ("Grundlagenvertrag") in December 1972, which recognized "two German states in one German Nation", East and West Germany were accepted as full members of the United Nations. West German opinion polls in the 1980s show that less than 10 percent of respondents expected a re-unification to occur during their lifetime ([Herdegen 1992](#)).

rapidly began to disintegrate. Only eleven months later East and West Germany were formally reunified on 3 October 1990. In June 1991 the German parliament voted to relocate the seat of the parliament and the majority of the federal ministries back to Berlin. As East and West Berlin again became part of the same city, suburban and underground rail lines and utility networks were rapidly reconnected. The reunification of the city was also accompanied by some urban regeneration initiatives and we include controls for these policies in our empirical analysis below.

### 3 Theoretical Model

To guide our empirical analysis, we develop a model in which the internal structure of the city is driven by a tension between agglomeration forces (in the form of production and residential externalities) and dispersion forces (in the form of commuting costs and an inelastic supply of land).<sup>14</sup> Our key contribution is to develop an empirically tractable quantitative version of the canonical urban model. This quantitative model allows for asymmetries in locational fundamentals and transport access across locations, and can be fitted to detailed data on the spatial distribution of economic activity within cities.

We consider a city embedded within a wider economy. The city consists of a set of discrete locations or blocks, which are indexed by  $i = 1, \dots, S$ . The city is populated by an endogenous measure of  $H$  workers, who are perfectly mobile within the city and larger economy. Each block has an effective supply of floor space  $L_i$ . Floor space can be used commercially or residentially, and we denote the endogenous fractions of floor space allocated to commercial and residential use by  $\theta_i$  and  $1 - \theta_i$ , respectively.

Workers decide whether or not to move to the city before observing idiosyncratic utility shocks for each possible pair of residence and employment locations within the city. If a worker decides to move to the city, they observe these realizations for idiosyncratic utility, and pick the pair of residence and employment locations within the city that maximizes their utility. Population mobility between the city and the wider economy implies that the expected utility from moving to the city equals the reservation level of utility in the wider economy  $\bar{U}$ . Firms produce a single final good, which is costlessly traded within the city and larger economy, and is chosen as the numeraire ( $p = 1$ ).<sup>15</sup>

Locations differ in terms of their final goods productivity, residential amenities, supply of floor space and access to the transport network, which determines travel times between any two locations in the city. We first develop the model with exogenous values of these location characteristics, before introducing endogenous agglomeration forces below.

---

<sup>14</sup>A more detailed discussion of the model and the technical derivations of all expressions and results reported in this section are contained in a separate web appendix.

<sup>15</sup>We follow the canonical urban model in assuming a single tradable final good and examine the ability of this canonical model to account quantitatively for the observed impact of division and reunification. In the web appendix, we discuss an extension of the model to introduce a non-traded good.

### 3.1 Workers

Workers are risk neutral and have preferences that are linear in an aggregate consumption index:  $U_{ij\omega} = C_{ij\omega}$ , where  $C_{ij\omega}$  denotes the aggregate consumption index for worker  $\omega$  residing in block  $i$  and working in block  $j$ .<sup>16</sup> This aggregate consumption index depends on consumption of the single final good ( $c_{ij\omega}$ ), consumption of residential floor space ( $\ell_{ij\omega}$ ), and three other components. First, residential amenities ( $B_i$ ) that capture common characteristics that make a block a more or less attractive place to live (e.g. leafy streets and scenic views). Second, the disutility from commuting from residence block  $i$  to workplace block  $j$  ( $d_{ij} \geq 1$ ). Third, there is an idiosyncratic shock that is specific to individual workers and varies with the worker's blocks of employment and residence ( $z_{ij\omega}$ ). This idiosyncratic shock captures the idea that individual workers can have idiosyncratic reasons for living and working in different parts of the city. In particular, the aggregate consumption index is assumed to take the Cobb-Douglas form:<sup>17</sup>

$$C_{ij\omega} = \frac{B_i z_{ij\omega}}{d_{ij}} \left( \frac{c_{ij\omega}}{\beta} \right)^\beta \left( \frac{\ell_{ij\omega}}{1-\beta} \right)^{1-\beta}, \quad 0 < \beta < 1, \quad (1)$$

where the iceberg commuting cost  $d_{ij} = e^{\kappa\tau_{ij}} \in [1, \infty)$  increases with the travel time between blocks  $i$  and  $j$  ( $\tau_{ij}$ ). Travel time is measured in minutes and is computed based on the transport network, as discussed further in the data section (Section 4). The parameter  $\kappa$  controls the size of commuting costs. Although we model commuting costs in terms of utility, there is an isomorphic formulation in terms of a reduction in effective units of labor, because the iceberg commuting cost  $d_{ij} = e^{\kappa\tau_{ij}}$  enters the indirect utility function (3) below multiplicatively. As a result, commuting costs are proportional to wages, and hence this specification captures changes over time in the opportunity cost of travel time.

We model the heterogeneity in the utility that workers derive from living and working in different parts of the city following [McFadden \(1974\)](#) and [Eaton and Kortum \(2002\)](#). For each worker  $\omega$  living in block  $i$  and commuting to block  $j$ , the idiosyncratic component of utility ( $z_{ij\omega}$ ) is drawn from an independent Fréchet distribution:

$$F(z_{ij\omega}) = e^{-T_i E_j z_{ij\omega}^{-\epsilon}}, \quad T_i, E_j > 0, \epsilon > 1, \quad (2)$$

where the scale parameter  $T_i > 0$  determines the average utility derived from living in block  $i$ ; the scale parameter  $E_j$  determines the average utility derived from working in block  $j$ ; and the shape parameter  $\epsilon > 1$  controls the dispersion of idiosyncratic utility.

After observing her realizations for idiosyncratic utility for each pair of residence and employment locations, each worker chooses her blocks of residence and employment to maximize her utility, taking as given residential amenities, goods prices, factor prices, and the location decisions of other workers and firms. Therefore workers sort across pairs of residence and employment locations depending on their idiosyncratic preferences and the characteristics of these locations. The indirect utility from residing in block  $i$  and

<sup>16</sup>To simplify the exposition, throughout the paper, we index a worker's block of residence by  $i$  or  $r$  and her block of employment by  $j$  or  $s$  unless otherwise indicated.

<sup>17</sup>For empirical evidence using US data in support of the constant housing expenditure share implied by the Cobb-Douglas functional form, see [Davis and Ortalo-Magné \(2011\)](#). The role played by residential amenities in influencing utility is emphasized in the literature following [Roback \(1982\)](#). See [Albouy \(2008\)](#) for a recent prominent contribution.

working in block  $j$  can be expressed in terms of wages at the block of employment ( $w_j$ ), commuting costs ( $d_{ij}$ ), residential floor prices ( $Q_i$ ), and the common ( $B_i$ ) and idiosyncratic ( $z_{ij\omega}$ ) components of amenities:<sup>18</sup>

$$u_{ij\omega} = \frac{z_{ij\omega} B_i w_j Q_i^{\beta-1}}{d_{ij}}, \quad (3)$$

where we have used utility maximization and the choice of the final good as numeraire.

Since indirect utility is a monotonic function of the idiosyncratic shock ( $z_{ij\omega}$ ), which has a Fréchet distribution, it follows immediately that indirect utility for workers living in block  $i$  and working in block  $j$  also has a Fréchet distribution. Each worker chooses the bilateral commute that offers her the maximum utility, where the maximum of a sequence of Fréchet distributed random variables is itself Fréchet distributed. Using these bilateral and multilateral distributions of utility, the probability that a worker chooses to live in block  $i$  and work in block  $j$  is:

$$\pi_{ij} = \frac{T_i E_j \left( d_{ij} Q_i^{1-\beta} \right)^{-\epsilon} (B_i w_j)^\epsilon}{\sum_{r=1}^S \sum_{s=1}^S T_r E_s \left( d_{rs} Q_r^{1-\beta} \right)^{-\epsilon} (B_r w_s)^\epsilon} \equiv \frac{\Phi_{ij}}{\Phi}. \quad (4)$$

Summing these probabilities across workplaces for a given residence, we obtain the overall probability that a worker resides in block  $i$  ( $\pi_{Ri}$ ), while summing these probabilities across residences for a given workplace, we obtain the overall probability that a worker works in block  $j$  ( $\pi_{Mj}$ ):

$$\pi_{Ri} = \sum_{j=1}^S \pi_{ij} = \frac{\sum_{j=1}^S \Phi_{ij}}{\Phi}, \quad \pi_{Mj} = \sum_{i=1}^S \pi_{ij} = \frac{\sum_{i=1}^S \Phi_{ij}}{\Phi}. \quad (5)$$

These residential and workplace choice probabilities have an intuitive interpretation. The idiosyncratic shock to preferences  $z_{ij\omega}$  implies that individual workers choose different bilateral commutes when faced with the same prices  $\{Q_i, w_j\}$ , commuting costs  $\{d_{ij}\}$  and location characteristics  $\{B_i, T_i, E_j\}$ . Other things equal, workers are more likely to live in block  $i$ , the more attractive its amenities  $B_i$ , the higher its average idiosyncratic utility as determined by  $T_i$ , the lower its residential floor prices  $Q_i$ , and the lower its commuting costs  $d_{ij}$  to employment locations. Other things equal, workers are more likely to work in block  $j$ , the higher its wage  $w_j$ , the higher its average idiosyncratic utility as determined by  $E_j$ , and the lower its commuting costs  $d_{ij}$  from residential locations.

As discussed above, although we interpret the idiosyncratic shock as affecting utility, there is an isomorphic interpretation of the model in which the idiosyncratic shock applies to effective units of labor (since  $z_{ij\omega}$  enters multiplicatively with  $w_j$  in (3)). Therefore the endogenous sorting of workers across locations implies that both residence and employment locations differ in the composition of workers in terms of idiosyncratic draws for utility or effective units of labor. Residential locations with higher values of  $T_i$  have higher average draws of utility (or effective units of labor). Similarly, employment locations with higher values of  $E_j$  have higher average draws of utility (or effective units of labor). To ensure that the

<sup>18</sup>We make the standard assumption in the urban literature that income from land is accrued by absentee landlords and not spent within the city, although it is also possible to consider the case where it is redistributed lump sum to workers.

general equilibrium of the model remains tractable, and because we do not observe worker characteristics in our data, we abstract from other dimensions of worker heterogeneity besides the idiosyncratic shock to preferences or effective units of labor.

These residential and workplace choice probabilities imply a gravity equation for bilateral commuting flows. Conditional on living in block  $i$ , the probability that a worker commutes to block  $j$  is:

$$\pi_{ij|i} = \frac{E_j (w_j/d_{ij})^\epsilon}{\sum_{s=1}^S E_s (w_s/d_{is})^\epsilon}, \quad (6)$$

where terms in  $\{Q_i, T_i, B_i\}$  have cancelled from the numerator and denominator. Therefore the probability of commuting to block  $j$  conditional on living in block  $i$  depends on the wage ( $w_j$ ), average utility draw ( $E_j$ ) and commuting costs ( $d_{ij}$ ) of employment location  $j$  in the numerator (“bilateral resistance”) as well as the wage ( $w_s$ ), average utility draw ( $E_s$ ) and commuting costs ( $d_{is}$ ) for all other possible employment locations  $s$  in the denominator (“multilateral resistance”).

Using these conditional commuting probabilities, we obtain the following commuting market clearing condition that equates the measure of workers employed in block  $j$  ( $H_{Mj}$ ) with the measure of workers choosing to commute to block  $j$ :

$$H_{Mj} = \sum_{i=1}^S \frac{E_j (w_j/d_{ij})^\epsilon}{\sum_{s=1}^S E_s (w_s/d_{is})^\epsilon} H_{Ri}, \quad (7)$$

where  $H_{Ri}$  is the measure of residents in block  $i$ . Since there is a continuous measure of workers residing in each location, there is no uncertainty in the supply of workers to each employment location. Our formulation of workers’ commuting decisions implies that the supply of commuters to each employment location  $j$  in (7) is a continuously increasing function of its wage relative to other locations.<sup>19</sup>

Expected worker income conditional on living in block  $i$  is equal to the wages in all possible employment locations weighted by the probabilities of commuting to those locations conditional on living in  $i$ :

$$\mathbb{E} [w_s|i] = \sum_{s=1}^S \frac{E_s (w_s/d_{is})^\epsilon}{\sum_{r=1}^S E_r (w_r/d_{ir})^\epsilon} w_s, \quad (8)$$

Therefore expected worker income is high in blocks that have low commuting costs (low  $d_{i,s}$ ) to high-wage employment locations.<sup>20</sup>

Finally, population mobility implies that the expected utility from moving to the city is equal to the reservation level of utility in the wider economy ( $\bar{U}$ ):

$$\mathbb{E} [u] = \gamma \left[ \sum_{r=1}^S \sum_{s=1}^S T_r E_s (d_{rs} Q_r^{1-\beta})^{-\epsilon} (B_r w_s)^\epsilon \right]^{1/\epsilon} = \bar{U}, \quad (9)$$

<sup>19</sup>This feature of the model is not only consistent with the gravity equation literature on commuting flows discussed above but also greatly simplifies the quantitative analysis of the model. In the absence of heterogeneity in worker productivity, small changes in wages can induce all workers residing in one location to start or stop commuting to another location, which is both empirically implausible and complicates the determination of general equilibrium with asymmetric locations.

<sup>20</sup>For simplicity, we model agents and workers as synonymous, which implies that labor is the only source of income. More generally, it is straightforward to extend the analysis to introduce families, where each worker has a fixed number of dependents that consume but do not work, and/or to allow agents to have a constant amount of non-labor income.

where  $\mathbb{E}$  is the expectations operator and the expectation is taken over the distribution for the idiosyncratic component of utility;  $\gamma = \Gamma\left(\frac{\epsilon-1}{\epsilon}\right)$  and  $\Gamma(\cdot)$  is the Gamma function.

### 3.2 Production

We follow the canonical urban model in assuming a single final good that is costlessly traded within the city and the larger economy.<sup>21</sup> Final goods production occurs under conditions of perfect competition and constant returns to scale. For simplicity, we assume that the production technology takes the Cobb-Douglas form, so that output of the final good in block  $j$  ( $y_j$ ) is:

$$y_j = A_j H_{Mj}^\alpha L_{Mj}^{1-\alpha}, \quad (10)$$

where  $A_j$  is final goods productivity and  $L_{Mj}$  is the measure of floor space used commercially.

Firms choose their block of production and their inputs of workers and commercial floor space to maximize profits, taking as given final goods productivity  $A_j$ , the distribution of idiosyncratic utility, goods and factor prices, and the location decisions of other firms and workers. Profit maximization implies that equilibrium employment is increasing in productivity ( $A_j$ ), decreasing in the wage ( $w_j$ ), and increasing in commercial floor space ( $L_{Mj}$ ):

$$H_{Mj} = \left(\frac{\alpha A_j}{w_j}\right)^{\frac{1}{1-\alpha}} L_{Mj}, \quad (11)$$

where the equilibrium wage is determined by the requirement that the demand for workers in each employment location (11) equals the supply of workers choosing to commute to that location (7).

From the first-order conditions for profit maximization and the requirement that zero profits are made if the final good is produced, equilibrium commercial floor prices ( $q_j$ ) in each block with positive employment must satisfy:

$$q_j = (1 - \alpha) \left(\frac{\alpha}{w_j}\right)^{\frac{\alpha}{1-\alpha}} A_j^{\frac{1}{1-\alpha}}. \quad (12)$$

Intuitively, firms in blocks with higher productivity ( $A_j$ ) and/or lower wages ( $w_j$ ) are able to pay higher commercial floor prices and still make zero profits.

### 3.3 Land Market Clearing

Land market equilibrium requires no-arbitrage between the commercial and residential use of floor space after taking into account the tax equivalent of land use regulations. The share of floor space used commercially ( $\theta_i$ ) is:

$$\begin{aligned} \theta_i &= 1 & \text{if } q_i > \xi_i Q_i, \\ \theta_i &= 0 & \text{if } q_i < \xi_i Q_i, \\ \theta_i &\in [0, 1] & \text{if } q_i = \xi_i Q_i, \end{aligned} \quad (13)$$

---

<sup>21</sup>Even during division, there was substantial trade between West Berlin and West Germany. In 1963, the ratio of exports to GDP in West Berlin was around 70 percent, with West Germany the largest trade partner. Overall, industrial production accounted for around 50 percent of West Berlin's GDP in this year ([American Embassy 1965](#)).

where  $\xi_i \geq 1$  captures one plus the tax equivalent of land use regulations that restrict commercial land use relative to residential land use. We allow this wedge between commercial and residential floor prices to vary across blocks.

Therefore floor space in each block is either allocated entirely to commercial use ( $q_i > \xi_i Q_i$  and  $\theta_i = 1$ ), allocated entirely to residential use ( $q_i < \xi_i Q_i$  and  $\theta_i = 0$ ), or allocated to both uses ( $q_i = \xi_i Q_i$  and  $\theta_i \in (0, 1)$ ). We assume that the observed price of floor space in the data is the maximum of the commercial and residential price of floor space:  $Q_i = \max\{q_i, Q_i\}$ . Hence the relationship between observed, commercial and residential floor prices can be summarized as:

$$\begin{aligned} Q_i &= q_i, & q_i &> \xi_i Q_i, & \theta_i &= 1, \\ Q_i &= q_i, & q_i &= \xi_i Q_i, & \theta_i &\in (0, 1), \\ Q_i &= Q_i, & q_i &< \xi_i Q_i, & \theta_i &= 0. \end{aligned} \tag{14}$$

We follow the standard approach in the urban literature of assuming that floor space  $L$  is supplied by a competitive construction sector that uses geographic land  $K$  and capital  $M$  as inputs. Following [Combes, Duranton, and Gobillon \(2014\)](#) and [Epple, Gordon, and Sieg \(2010\)](#), we assume that the production function takes the Cobb-Douglas form:  $L_i = M_i^\mu K_i^{1-\mu}$ .<sup>22</sup> Therefore the corresponding dual cost function for floor space is  $Q_i = \mu^{-\mu} (1 - \mu)^{-(1-\mu)} \mathbb{P}^\mu \mathbb{R}_i^{1-\mu}$ , where  $Q_i = \max\{q_i, Q_i\}$  is the price for floor space,  $\mathbb{P}$  is the common price for capital across all blocks, and  $\mathbb{R}_i$  is the price for geographic land. Since the price for capital is the same across all locations, the relationships between the quantities and prices of floor space and geographical land area can be summarized as:

$$L_i = \varphi_i K_i^{1-\mu} \tag{15}$$

$$Q_i = \chi \mathbb{R}_i^{1-\mu}, \tag{16}$$

where  $\varphi_i = M_i^\mu$  captures the density of development and  $\chi$  is a constant.

Residential land market clearing implies that the demand for residential floor space equals the supply of floor space allocated to residential use in each location:  $(1 - \theta_i) L_i$ . Using utility maximization for each worker and taking expectations over the distribution for idiosyncratic utility, this residential land market clearing condition can be expressed as:

$$\mathbb{E}[\ell_i] H_{Ri} = (1 - \beta) \frac{\mathbb{E}[w_s | i] H_{Ri}}{Q_i} = (1 - \theta_i) L_i. \tag{17}$$

Commercial land market clearing requires that the demand for commercial floor space equals the supply of floor space allocated to commercial use in each location:  $\theta_j L_j$ . Using the first-order conditions for profit maximization, this commercial land market clearing condition can be written as:

$$\left( \frac{(1 - \alpha) A_j}{q_j} \right)^{\frac{1}{\alpha}} H_{Mj} = \theta_j L_j. \tag{18}$$

---

<sup>22</sup>Empirically, we find that this Cobb-Douglas assumption provides a good approximation to confidential micro data on property transactions for Berlin that are available from 2000-2012.

When both residential and commercial land market clearing ((17) and (18) respectively) are satisfied, total demand for land equals the total supply of land:

$$(1 - \theta_i) L_i + \theta_i L_i = L_i = \varphi_i K_i^{1-\mu}. \quad (19)$$

### 3.4 General Equilibrium with Exogenous Location Characteristics

We begin by characterizing the properties of a benchmark version of the model in which location characteristics are exogenous, before relaxing this assumption to introduce endogenous agglomeration forces below. Throughout the following we use bold math font to denote vectors. Given the model's parameters  $\{\alpha, \beta, \mu, \epsilon, \kappa\}$ , the reservation level of utility in the wider economy  $\bar{U}$  and vectors of exogenous location characteristics  $\{\mathbf{T}, \mathbf{E}, \mathbf{A}, \mathbf{B}, \boldsymbol{\varphi}, \mathbf{K}, \boldsymbol{\xi}, \boldsymbol{\tau}\}$ , the general equilibrium of the model is referenced by the six vectors  $\{\boldsymbol{\pi}_M, \boldsymbol{\pi}_R, \mathbf{Q}, \mathbf{q}, \mathbf{w}, \boldsymbol{\theta}\}$  and total city population  $H$ . These seven components of the equilibrium vector are determined by the following system of seven equations: population mobility (9), the residential choice probability ( $\pi_{Ri}$  in (5)), the workplace choice probability ( $\pi_{Mj}$  in (5)), commercial land market clearing (18), residential land market clearing (17), profit maximization and zero profits (12), and no-arbitrage between alternative uses of land (13).

**Proposition 1** *Assuming exogenous, finite and strictly positive location characteristics ( $T_i \in (0, \infty)$ ,  $E_i \in (0, \infty)$ ,  $\varphi_i \in (0, \infty)$ ,  $K_i \in (0, \infty)$ ,  $\xi_i \in (0, \infty)$ ,  $\tau_{ij} \in (0, \infty) \times (0, \infty)$ ), and exogenous finite and non-negative final goods productivity  $A_i \in [0, \infty)$  and residential amenities  $B_i \in [0, \infty)$ , there exists a unique general equilibrium vector  $\{\boldsymbol{\pi}_M, \boldsymbol{\pi}_R, H, \mathbf{Q}, \mathbf{q}, \mathbf{w}, \boldsymbol{\theta}\}$ .*

**Proof.** See Lemmas A1-A3 and the proofs of Propositions A1-A2 in Section A2 of the web appendix. ■

In this case of exogenous location characteristics, the distribution of workers and residents across locations is determined by exogenous differences in productivity  $A_i$  and amenities  $B_i$  combined with the model's dispersion forces of commuting costs, diminishing marginal returns to commercial land use, and diminishing marginal returns to residential land use. These dispersion forces ensure the existence of a unique distribution of economic activity.

We establish a number of properties of the general equilibrium with exogenous location characteristics in the web appendix. Since the support of the Fréchet distribution is unbounded from above, all blocks with strictly positive amenities ( $B_i$ ) attract a strictly positive measure of residents ( $H_{Ri}$ ), and all blocks with strictly positive wages ( $w_j$ ) attract a strictly positive measure of employment ( $H_{Mj}$ ). Therefore, if all location characteristics  $\{\mathbf{T}, \mathbf{E}, \mathbf{A}, \mathbf{B}, \boldsymbol{\varphi}, \mathbf{K}, \boldsymbol{\xi}, \boldsymbol{\tau}\}$  are exogenous, finite and strictly positive, all locations have positive residents and employment, and are incompletely specialized between commercial and residential land use. Furthermore, assuming that all other location characteristics  $\{\mathbf{T}, \mathbf{E}, \boldsymbol{\varphi}, \mathbf{K}, \boldsymbol{\xi}, \boldsymbol{\tau}\}$  are exogenous, finite and strictly positive, a necessary and sufficient condition for zero residents is  $B_i = 0$ . Similarly, a necessary and sufficient condition for zero employment is  $w_j = 0$ , which in turn requires zero final goods productivity  $A_j = 0$ . Therefore the model rationalizes zero workplace employment with zero productivity ( $A_i$ ) and zero residence employment with zero amenities ( $B_i$ ).

### 3.5 Introducing Agglomeration Forces

Having established the properties of the model with exogenous location characteristics, we now introduce endogenous agglomeration forces. We allow final goods productivity to depend on production fundamentals ( $a_j$ ) and production externalities ( $\Upsilon_j$ ). Production fundamentals capture features of physical geography that make a location more or less productive independently of the surrounding density of economic activity (for example access to natural water). Production externalities impose structure on how the productivity of a given block is affected by the characteristics of other blocks. Specifically, we follow the standard approach in urban economics of modeling these externalities as depending on the travel-time weighted sum of workplace employment density in surrounding blocks:<sup>23</sup>

$$A_j = a_j \Upsilon_j^\lambda, \quad \Upsilon_j \equiv \sum_{s=1}^S e^{-\delta \tau_{js}} \left( \frac{H_{Ms}}{K_s} \right), \quad \lambda \geq 0, \delta \geq 0. \quad (20)$$

where  $H_{Ms}/K_s$  is workplace employment density per unit of geographical land area; production externalities decline with travel time ( $\tau_{js}$ ) through the iceberg factor  $e^{-\delta \tau_{js}} \in (0, 1]$ ;  $\delta$  determines their rate of spatial decay; and  $\lambda$  controls their relative importance in determining overall productivity.<sup>24</sup>

We model the externalities in workers' residential choices analogously to the externalities in firms' production choices. We allow residential amenities to depend on residential fundamentals ( $b_i$ ) and residential externalities ( $\Omega_i$ ). Residential fundamentals capture features of physical geography that make a location a more or less attractive place to live independently of the surrounding density of economic activity (for example green areas). Residential externalities again impose structure on how the amenities in a given block are affected by the characteristics of other blocks. Specifically, we adopt a symmetric specification as for production externalities, and model residential externalities as depending on the travel-time weighted sum of residential employment density in surrounding blocks:

$$B_i = b_i \Omega_i^\eta, \quad \Omega_i \equiv \sum_{s=1}^S e^{-\rho \tau_{is}} \left( \frac{H_{Rs}}{K_s} \right), \quad \eta \geq 0, \rho \geq 0, \quad (21)$$

where  $H_{Rs}/K_s$  is residence employment density per unit of geographical land area; residential externalities decline with travel time ( $\tau_{is}$ ) through the iceberg factor  $e^{-\rho \tau_{is}} \in (0, 1]$ ;  $\rho$  determines their rate of spatial decay; and  $\eta$  controls their relative importance in overall residential amenities.

The introduction of these agglomeration forces generates the potential for multiple equilibria in the model if these agglomeration forces are sufficiently strong relative to the exogenous differences in characteristics across locations. Even in the presence of such multiple equilibria, there exists a one-to-one mapping from known values of the model's parameters  $\{\alpha, \beta, \mu, \epsilon, \kappa, \lambda, \delta, \eta, \rho\}$  and the observed data

<sup>23</sup>While the canonical interpretation of these production externalities in the urban economics literature is knowledge spillovers, as in [Alonso \(1964\)](#), [Fujita and Ogawa \(1982\)](#), [Lucas \(2000\)](#), [Mills \(1967\)](#), [Muth \(1969\)](#), and [Sveikauskas \(1975\)](#), other interpretations are possible, as considered in [Duranton and Puga \(2004\)](#).

<sup>24</sup>We make the standard assumption that production externalities depend on employment density per unit of geographical land area  $K_i$  (rather than per unit of floor area  $L_i$ ) to capture the role of higher densities of development  $\varphi_i$  (higher ratios of floor space to geographical land area) in increasing the surrounding concentration of economic activity.

$\{\mathbb{Q}, \mathbf{H}_M, \mathbf{H}_R, \mathbf{K}, \boldsymbol{\tau}\}$  to adjusted values of overall productivity, overall amenities, production fundamentals, residential fundamentals and the density of development  $\{\tilde{A}_i, \tilde{B}_i, \tilde{a}_i, \tilde{b}_i, \tilde{\varphi}_i\}$ , as shown in subsection 3.6 below. These adjusted values control for other location characteristics that enter the model isomorphically to production fundamentals, residential fundamentals and the density of development, as also discussed in subsection 3.6 below. Given known model parameters and the observed data, this one-to-one mapping can be used to recover unique values of the adjusted location characteristics, irrespective of whether the observed equilibrium is unique or one of several possible equilibria (see Proposition 2 below).

In our structural estimation in section 7, we estimate both the model's parameters and the unobserved adjusted location characteristics. We use the property that the adjusted location characteristics are structural residuals of the model that are one-to-one functions of the observed data and parameters. We use these structural residuals and the exogenous variation from Berlin's division and reunification to construct moment conditions in terms of the model's parameters. In principle, these moment conditions need not uniquely identify the model parameters, because the objective function defined by them need not be globally concave. For example, there could be multiple local minima corresponding to different equilibria of the model with different parameter values. In practice, we find that the objective function is well behaved in the parameter space, and that these moment conditions determine a unique parameter vector, as discussed further in subsection 7.4 below. We find that this parameter vector takes similar values for both division and reunification.

### 3.6 Recovering Location Characteristics

We now show that there is a unique mapping from known values of the model's parameters and the observed data on the endogenous variables to the unobserved location characteristics. We also show that the model has a recursive structure, so that overall adjusted productivity, amenities and the density of development can be determined  $\{\tilde{A}_i, \tilde{B}_i, \tilde{\varphi}_i\}$ , irrespective of whether these location characteristics are exogenous or endogenous, and irrespective of the breakdown of productivity and amenities into the contributions of externalities  $\{\Upsilon_i, \Omega_i\}$  and adjusted fundamentals  $\{\tilde{a}_i, \tilde{b}_i\}$ .

**Proposition 2 (i)** *Given known values for the parameters  $\{\alpha, \beta, \mu, \epsilon, \kappa\}$  and the observed data  $\{\mathbb{Q}, \mathbf{H}_M, \mathbf{H}_R, \mathbf{K}, \boldsymbol{\tau}\}$ , there exist unique vectors of the unobserved location characteristics  $\{\tilde{\mathbf{A}}^*, \tilde{\mathbf{B}}^*, \tilde{\boldsymbol{\varphi}}^*\}$  that are consistent with the data being an equilibrium of the model.*

**(ii)** *Given known values for the parameters  $\{\alpha, \beta, \mu, \epsilon, \kappa, \lambda, \delta, \eta, \rho\}$  and the observed data  $\{\mathbb{Q}, \mathbf{H}_M, \mathbf{H}_R, \mathbf{K}, \boldsymbol{\tau}\}$ , there exist unique vectors of the unobserved location characteristics  $\{\tilde{\mathbf{a}}^*, \tilde{\mathbf{b}}^*, \tilde{\boldsymbol{\varphi}}^*\}$  that are consistent with the data being an equilibrium of the model.*

**Proof.** See the proofs of Propositions A3-A4 in Section A3 of the web appendix. ■

We emphasize that Proposition 2 is derived for known parameter values and that we return to the estimation of the model's parameters in Section 7 below. The intuition for why the mapping in Proposition

2 is unique even in the presence of multiple equilibria is that the observed data, parameters and structure of the model contain enough information to uniquely determine the unobserved location characteristics.

Given observed floor prices and wages (which can be determined from observed employment), we can use profit maximization and zero profits to determine the value that adjusted productivity must take in order for the data to be an equilibrium of the model (equation (12)). Similarly, given observed floor prices, observed residential employment and wages (which can be determined from observed employment), we can use utility maximization and population mobility to determine the value that adjusted amenities must take in order for the data to be an equilibrium of the model (equation (5)). Finally, using the implied demands for commercial and residential floor space and market clearing for floor space, we can recover the value that the adjusted density of development must take in order for the data to be an equilibrium of the model.

These relationships based on profit maximization, zero profits, utility maximization, population mobility and land market clearing hold irrespective of whether productivity, amenities and the density of development are exogenous or endogenous (since agents are atomistic and take the behavior of others as given). They also hold irrespective of the relative importance of the two components of productivity and amenities (externalities and fundamentals). Therefore, using the recursive structure of the model, the adjusted values of overall productivity, amenities and the density of development  $\{\tilde{A}, \tilde{B}, \tilde{\varphi}\}$  can be determined using a subset of the parameters  $\{\alpha, \beta, \mu, \epsilon, \kappa\}$  and the observed data. Having determined overall productivity, amenities and the density of development, the relative importance of externalities  $\{\Upsilon, \Omega\}$  and adjusted fundamentals  $\{\tilde{a}, \tilde{b}\}$  can be determined using the remaining parameters  $\{\lambda, \delta, \eta, \rho\}$  and the observed data.

Proposition 2 and its proof also highlight that some variables and parameters enter the model isomorphically. In particular, in the labor market, the adjusted wage ( $\tilde{w}_j$ ) includes the wage ( $w_j$ ) and the Fréchet scale parameter for each employment location ( $E_j^{1/\epsilon}$ ). On the production side, adjusted productivity ( $\tilde{A}_j$ ) includes productivity ( $A_j$ ) and the Fréchet scale parameter for each employment location ( $E_j^{\alpha/\epsilon}$ ). Similarly, adjusted production fundamentals ( $\tilde{a}_j$ ) includes production fundamentals ( $a_j$ ) and the Fréchet scale parameter for each employment location ( $E_j^{\alpha/\epsilon}$ ). On the consumption side, adjusted residential amenities ( $\tilde{B}_i$ ) includes residential amenities ( $B_i$ ), the Fréchet scale parameter for each residence location ( $T_i^{1/\epsilon}$ ), and the wedge between commercial and residential floor prices ( $\xi_i$ ). Similarly, adjusted residential fundamentals ( $\tilde{b}_i$ ) includes residential fundamentals ( $b_i$ ), the Fréchet scale parameter for each residence location ( $T_i^{1/\epsilon}$ ), and the wedge between commercial and residential floor prices ( $\xi_i$ ). Finally, in the land market, the adjusted density of development ( $\tilde{\varphi}_i$ ) includes the density of development ( $\varphi_i$ ) and other production and residential parameters discussed above.

Having solved for the adjusted location characteristics  $\{\tilde{A}_i, \tilde{B}_i, \tilde{\varphi}_i, \tilde{a}_i, \tilde{b}_i\}$ , we can recover the implied reservation level of utility in the wider economy  $\bar{U}$  and solve for all other endogenous variables of the model, including the bilateral commuting probabilities ( $\pi_{ij}$  and  $\pi_{ij|i}$ ).

### 3.7 Counterfactuals

Given known values for the model's parameters  $\{\alpha, \beta, \mu, \epsilon, \kappa, \lambda, \delta, \eta, \rho\}$ , the observed location characteristics  $\{K, \tau\}$  and the above solutions for the unobserved adjusted location characteristics  $\{\tilde{A}, \tilde{B}, \tilde{\varphi}, \tilde{a}, \tilde{b}\}$ ,

the model can be used to undertake counterfactuals for a variety of comparative statics (e.g. for the effects of constructing an underground line that reduces travel times between blocks). To undertake these counterfactuals, we need to take a stand on whether productivity, amenities and the density of development are exogenous or endogenous, and on the relative importance of externalities and fundamentals.

In our benchmark case of exogenous location characteristics, the model has a unique equilibrium, and hence these counterfactuals yield unique predictions for the impact of the comparative static on city structure. More generally, if agglomeration forces are sufficiently strong relative to exogenous differences in location characteristics, there is the potential for multiple equilibria in the model. In this case, the predictions of these counterfactuals can depend on which equilibrium is selected in the counterfactual. We solve for the counterfactual equilibrium using starting values from the initial equilibrium, which implies that our equilibrium selection rule is to search for the closest counterfactual equilibrium to the initial equilibrium.

When we solve for the counterfactual effects of division and reunification using our estimated values of agglomeration and dispersion forces, we hold productional fundamentals, residential fundamentals and the density of development constant at their values in the initial equilibrium. We show that the predicted effects of division and reunification in the estimated model with agglomeration forces are close to the observed effects, suggesting that the selected equilibrium is close to the observed equilibrium.

### 3.8 Berlin's Division and Reunification

We focus in our empirical analysis on West Berlin, since it remained a market-based economy after division and we therefore expect the mechanisms in the model to apply.<sup>25</sup> We capture the division of Berlin in the model by assuming infinite costs of trading the final good, infinite commuting costs ( $\kappa \rightarrow \infty$ ), infinite rates of decay of production externalities ( $\delta \rightarrow \infty$ ), and infinite rates of decay of residential externalities ( $\rho \rightarrow \infty$ ) across the Berlin Wall.

The model points to four key channels through which division affects the distribution of economic activity within West Berlin: a loss of employment opportunities in East Berlin, a loss of commuters from East Berlin, a loss of production externalities from East Berlin, and a loss of residential externalities from East Berlin. Each of these four effects reduces the expected utility from living in West Berlin, and hence reduces its overall population, as workers out migrate to West Germany. Furthermore, each of these effects is stronger for parts of West Berlin close to employment and residential concentrations in East Berlin, reducing floor prices, workplace employment and residence employment in these parts of West Berlin relative to those elsewhere in West Berlin. The mechanisms that restore equilibrium in the model are changes in wages and floor prices. Workplace and residence employment reallocate across locations within West Berlin and to West Germany, until wages and floor prices have adjusted such that firms make zero profits in all locations with positive production, workers are indifferent across all populated locations, and there are no-arbitrage opportunities in reallocating floor space between commercial and residential use.

---

<sup>25</sup>In contrast, the distribution of economic activity in East Berlin during division was heavily influenced by central planning, which is unlikely to mimic market forces.

Since reunification involves a re-integration of West Berlin with employment and residential concentrations in East Berlin, we would expect to observe the reverse pattern of results in response to reunification. But reunification need not necessarily have exactly the opposite effects from division. As discussed above, if agglomeration forces are sufficiently strong relative to the differences in fundamentals across locations, there can be multiple equilibria in the model. In this case, division could shift the distribution of economic activity in West Berlin between multiple equilibria, and reunification need not necessarily reverse the impact of division. More generally, the level and distribution of economic activity within East Berlin could have changed between the pre-war and division periods, so that reunification is a different shock from division. Notwithstanding these points, reintegration with employment and residential concentrations in East Berlin is predicted to raise relative floor prices, workplace employment and residence employment in the areas of West Berlin close to those concentrations.

## 4 Data Description

The quantitative analysis of our model requires four key sets of data: workplace employment, residence employment, the price of floor space and commuting times between locations. We have compiled these variables for Berlin at the block level for three years that cover the pre-war, division and reunification period. For simplicity we generally refer to these three years as 1936, 1986, and 2006 even though some of the data are from the closest available neighboring year. In addition to these main variables we have compiled data on a wide range of other block characteristics, commuting behavior, the dispersion of wages across districts, and also the price of floor space in 1928 and 1966. Below we briefly describe the data definitions and sources. A more detailed discussion is included in the web appendix.

Data for Berlin is available at a number of different levels of spatial disaggregation. The finest available disaggregation is statistical blocks (“Blöcke”). In 2006 the surface of Berlin was partitioned into 15,937 blocks, of which just under 9,000 are in the former West Berlin. We hold this block structure constant for all years in our data. These blocks have a mean area of about 50,000 square meters and an average 2005 population of 274 for the 12,192 blocks with positive 2005 population.<sup>26</sup> Blocks can be aggregated up to larger spatial units including statistical areas (“Gebiete”) and districts (“Bezirke”).<sup>27</sup>

Our measure of employment at the place of work for the reunification period is a count of the 2003 social security employment (“Sozialversicherungspflichtig Beschäftigte”) in each block, which was provided by the Statistical Office of Berlin (“Senatsverwaltung für Berlin”) in electronic form. We scale up social security employment in each block by the ratio of social security employment to total employment for Berlin as a whole. Data for the division period come from the printed records of the 1987 census, which reports total workplace employment by block. We construct comparable data for the pre-war period by combining

---

<sup>26</sup>There are a number of typically larger blocks that only contain water areas, forests, parks and other uninhabited areas. Approximately 29 percent of the area of Berlin in 2006 is covered by forests and parks, while another 7 percent is accounted for by lakes, rivers and canals (Statistical Yearbook of Berlin 2007).

<sup>27</sup>As discussed in Section 2, we use the 1938 district boundaries upon which the occupation sectors were based unless otherwise indicated.

data on district total private-sector workplace employment published in the 1933 census with the registered addresses of all firms on the Berlin company register (“Handelsregister”) in 1931. As described in detail in the web appendix, we use the number of firms in each block to allocate the 1933 district totals for private-sector workplace employment across blocks within districts. Finally, we allocate 1933 public-sector workplace employment across blocks using detailed information on the location of public administration buildings (including ministries, utilities and schools) immediately prior to the Second World War.

To construct employment at residence for the reunification period, we use data on the population of each block in 2005 from the Statistical Office of Berlin and scale the population data using district-level information on labor force participation.<sup>28</sup> Employment at residence for the division period is reported by block in the printed records of the 1987 census. To construct pre-war data on employment at residence, we use a tabulation in the 1933 census that lists the population of each street or segment of street in Berlin. As described in more detail in the web appendix, we use a concordance between streets and blocks to allocate the population of streets to individual blocks. We then again use labor force participation rates at the district level to scale the population data to obtain employment at residence by block.

Berlin has a long history of providing detailed assessments of land values, which have been carried out by the independent Committee of Valuation Experts (“Gutachterausschuss für Grundstückswerte”) in the post-war period. The committee currently has 50 members who are building surveyors, real estate practitioners and architects. Our land price data for 1986 and 2006 are the land values (“Bodenrichtwerte”) per square meter of geographical land area published by the Committee on detailed maps of Berlin which we have digitized and merged with the block structure. The Committee’s land values capture the fair market value of a square meter of land if it was undeveloped. While the Committee does not publish the details of the valuation procedure, the land values are based on recent market transactions. As a check on the Committee’s land values, we compare them to confidential micro data on property transactions that are available from 2000-2012. As shown in the web appendix, we find a high correlation between the land values reported by the Committee for 2006 and the land values that we compute from the property transactions data. Finally, the land value data also includes information on the typical density of development, measured as the ratio of floor space to ground area (“GFZ”).<sup>29</sup>

Our source of land price data for the pre-war period is [Kalweit \(1937\)](#). Kalweit was a chartered building surveyor (“Gerichtlich Beeideter Bausachverständiger”), who received a government commission for the assessment of land values in Berlin (“Baustellenwerte”) for 1936. These land values were intended to provide official and representative guides for private and public investors in Berlin’s real estate market. As with the modern land value data, they capture the fair market price of a square meter of undeveloped land and are reported for each street or segment of street in Berlin. Using ArcGIS, we matched the streets or segments of streets in [Kalweit \(1937\)](#) to blocks, and aggregated the street-level land price data to the block-level.<sup>30</sup>

---

<sup>28</sup>Empirically, labor force participation is relatively constant across districts within Berlin in all years of our dataset.

<sup>29</sup>Note that the Committee’s land values are completely different from the unit values (“Einheitswerte”) used to calculate property taxes. The current unit values are still based on an assessment (“Hauptfeststellung”) that took place as early as 1964 for the former West Germany and 1935 for the former East Germany. In contrast, the Committee’s land values are based on contemporaneous market transactions and are regularly updated.

<sup>30</sup>In robustness checks, we also use land value data for 1928 from [Kalweit \(1929\)](#) (which has the same structure as [Kalweit](#)

To convert land prices ( $\mathbb{R}_i$ ) to floor prices ( $\mathbb{Q}_i$ ), we use the assumption of a competitive construction sector with a Cobb-Douglas technology, as discussed in subsection 3.3 above.

Travel times are measured in minutes based on the transport network available in each year and assumed average travel speeds for each mode of transport. To determine travel times between each of the 15,937 blocks in our data, i.e. nearly 254 million ( $15,937 \times 15,937$ ) bilateral connections, we distinguish between travel times by public transport and car. As described in more detail in the web appendix, we construct minimum travel times by public transport for the three years using information on the underground railway (“U-Bahn”), suburban railway (“S-Bahn”), tram (“Strassenbahn”) and bus (“Bus”) network of Berlin in each year. We use ArcGIS to compute the fastest connection between each pair of blocks allowing passengers to combine all modes of public transport and walking to minimize travel time. We construct minimum driving times by car in 1986 and 2006 using an ArcGIS shape file of the street network of Berlin. For 1986 and 2006, we measure overall travel times by weighting public transport and car minimum travel times using district-level data on the proportion of journeys undertaken with these two modes of transport. For 1936, commuting to work by car was rare, and hence we use public transport minimum travel times.<sup>31</sup>

In addition to our main variables, we have compiled a number of other data, which are described in detail in the web appendix. First, we have data on observable block characteristics including, the location of parks and other green spaces, proximity to lakes, rivers and canals, proximity to schools, average noise level, the number of listed buildings, the extent of destruction during the Second World War, and urban regeneration programs and government buildings post reunification. Second, we have obtained survey data on commuting flows in Berlin in 1936, 1982 and 2008. Third, we have obtained data on average wages by workplace for each district of West Berlin in 1986.

## 5 Reduced-Form Results

In this section, we provide reduced-form evidence in support of the model’s qualitative predictions that complements our later structural estimation of the model. First, we use this reduced-form analysis to establish reorientations of land prices, workplace employment and residence employment within West Berlin following division and reunification without imposing the full structure of the model. Second, this reduced-form analysis enables us to demonstrate the robustness of these reorientations to the inclusion of a wide range of controls and provide evidence against alternative possible explanations.

### 5.1 Evolution of the Land Price Gradient over Time

In Figure 2, we display the spatial distribution of land prices across blocks for each year as a three-dimensional map. The main public parks and forests are shown in green and the main bodies of water are shown in blue. White areas correspond to other undeveloped areas including railways. Since we use the same vertical scale

---

1937), and for 1966 from the Committee of Valuation Experts (which has the same structure as the 1986 and 2006 data).

<sup>31</sup>Leyden (1933) reports data on travel by mode of transport in pre-war Berlin, in which travel by car accounts for less than 10 percent of all journeys.

for each figure, and land prices are normalized to have a mean of one in each year, the levels of the land price surfaces in each figure are comparable.

As apparent from Panel A of Figure 2, Berlin's land price gradient in 1936 was in fact approximately monocentric, with the highest values concentrated in the district Mitte. We measure the center of the pre-war Central Business District (CBD) as the intersection of Friedrich Strasse and Leipziger Strasse, close to the U-Bahn station "Stadtmitte." Around this central point, there are concentric rings of progressively lower land prices surrounding the pre-war CBD. Towards the Western edge of these concentric rings is the Kudamm ("Kurfürstendamm") in Charlottenburg and Wilmersdorf, which had developed into a fashionable shopping area in the decades leading up to the Second World War. This area lies to the West of the Tiergarten Park, which explains the gap in land prices between the Kudamm and Mitte. Panel A also shows the future line of the Berlin Wall (shown in gray font), including the inner boundary between East and West Berlin and the outer boundary that separated West Berlin from its East German hinterland.

To show relative land values in locations that subsequently became part of West Berlin, Panel B displays the 1936 distribution of land prices for only these locations. The two areas of West Berlin with the highest pre-war land prices were parts of the concentric ring around the pre-war CBD: the area around the Kudamm discussed above and a second area just West of Potsdamer Platz and the future line of the Berlin Wall. This second area was a concentration of commercial and retail activity surrounding the "Anhalter Bahnhof" mainline and suburban rail station. Neither of these areas contained substantial government administration, which was instead concentrated in Mitte in the future East Berlin, particularly around Wilhelmstrasse.

In Panel C, we examine the impact of division by displaying the 1986 distribution of land prices for West Berlin. Comparing Panels B and C, three main features stand out. First, land prices exhibit less dispersion and smaller peak values in West Berlin during division than in Greater Berlin during the pre-war period. Second, one of the pre-war land price peaks in West Berlin – the area just West of Potsdamer Platz – is entirely eliminated following division, as this area ceased to be an important center of commercial and retail activity. Third, West Berlin's CBD during division coincided with the other area of high pre-war land values in West Berlin around the Kudamm, which was relatively centrally located within West Berlin.

To examine the impact of reunification, Panel D displays the 2006 distribution of land prices across blocks within Berlin as a whole, while Panel E shows the same distribution but only for blocks in the former West Berlin. Comparing these two figures with the previous two figures, three main features are again apparent. First, land prices are more dispersed and have higher peak values following reunification than during division. Second, the area just West of Potsdamer Platz is re-emerging as a concentration of office and retail development with high land values. Third, Mitte is also re-emerging as a center of high land values. As in the pre-war period, the main government ministries are either concentrated in Mitte in the former East Berlin or around the Federal parliament ("Reichstag").

Figures A1 and A2 in the web appendix display the log difference in land prices from 1936-1986 and 1986-2006 for each block. As evident from these figures, the largest declines in land prices following division and the largest increases in land prices following reunification are along those segments of the Berlin Wall around the pre-war CBD. In contrast, there is little evidence of comparable declines in land prices along

other sections of the Berlin Wall. Therefore these results provide some first evidence that it is not proximity to the Berlin Wall *per se* that matters but the loss of access to the pre-war CBD. Regressing the growth in floor prices from 1986-2006 on the growth in floor prices from 1936-1986, we find an estimated coefficient (Conley standard error) of -0.262 (0.017) and an R-squared of 0.29, suggesting that the areas that experienced the largest decline in floor prices after division also experienced the largest growth in floor prices after reunification.

## 5.2 Difference-in-Difference Estimates

To establish the statistical significance of the reorientation of the floor price gradient and its robustness to the inclusion of controls, we estimate the following “difference-in-difference” specification for division and reunification separately:

$$\Delta \ln O_i = \alpha + \sum_{k=1}^K \mathbb{I}_{ik} \beta_k + \ln M_i \gamma + u_i, \quad (22)$$

where  $i$  denotes blocks;  $\Delta O_i$  is the change in an economic outcome of interest (floor prices, workplace employment, residence employment);  $\alpha$  is a constant;  $\mathbb{I}_{ik}$  is an indicator variable for whether block  $i$  lies within a distance grid cell  $k$  from the pre-war CBD;  $\beta_k$  are coefficients to be estimated;  $M_i$  are time-invariant observable block characteristics (such as proximity to parks and lakes);  $\gamma$  captures changes over time in the premium to these time-invariant observable block characteristics; and  $u_i$  is a stochastic error.

This specification allows for a time-invariant fixed effect in the level of the economic outcome of interest, which is differenced out when we take differences before and after division (or reunification). This specification also allows for a common time effect of division or reunification across all blocks, which is captured in the constant  $\alpha$ . We begin by considering distance grid cells of 500 meter intervals. Since the minimum distance to the pre-war CBD in West Berlin is around 0.75 kilometers, our first distance grid cell is for blocks with distances less than 1.25 kilometers. We include grid cells for blocks with distance up to 3.25-3.75 kilometers, so that the excluded category is blocks more than 3.75 kilometers from the pre-war CBD.<sup>32</sup> This grid cells specification allows for a flexible functional form for the relationship between changes in block economic outcomes and distance from the pre-war CBD. In these reduced-form regressions, we take the location of the pre-war CBD as given, whereas in the structural model its location is endogenously determined. In the next section, we show that we find similar reduced-form results using other non-parametric approaches that do not require us to specify grid cells, such as locally-weighted linear least squares.

We show that our results are robust to two alternative approaches to controlling for spatial correlation in the error term  $u_i$ . In our baseline specification in the paper, we report Heteroscedasticity and Autocorrelation Consistent (HAC) standard errors following Conley (1999), which allow for spatial correlation in the errors across neighboring blocks with distances less than a specified threshold.<sup>33</sup> As a robustness check, the web appendix reports standard errors clustered on statistical areas (“Gebiete”), which allows for a general

<sup>32</sup>The number of West Berlin blocks with floor price data in all three years in each grid cell (from nearest to furthest from the pre-war CBD) are: 32, 48, 60, 111, 171 and 195. The maximum distance to the pre-war CBD in West Berlin is around 23 kilometers.

<sup>33</sup>We use a threshold of 0.5 kilometers, where the median block in Berlin has 19 other blocks within 0.5 kilometers.

correlation structure in the errors across blocks within areas, but assumes that the errors are independent across areas (see for example [Bertrand, Duflo, and Mullainathan 2004](#)).

Table 1 reports the results of estimating our baseline specification (22) for division.<sup>34</sup> The dependent variable in Columns (1)-(5) is the log difference in the price of floor space from 1936-86. In Column (1) we include only the distance grid cells, and find a negative and statistically significant effect of proximity to the pre-war CBD, which declines monotonically with distance from the pre-war CBD. On average, West Berlin blocks within the first grid cell experience around a 55 percent reduction in the price of floor space between 1936 and 1986 (since  $1 - e^{-0.800} = 0.55$ ) relative to those more than 3.75 kilometers away from the pre-war CBD. Together the six grid cells alone explain around one quarter of the variation in the change in the price of floor space following division ( $R^2 = 0.26$ ), suggesting a powerful effect of proximity to the pre-war concentration of economic activity in East Berlin.

In Column (2), we show that these results are robust to including district fixed effects, which focuses solely on within-district variation in proximity to the pre-war CBD. Column (3) examines whether it is really proximity to the pre-war CBD that matters by including analogous 500 meter grid cells for distance to the closest point on (a) the inner boundary between East and West Berlin and (b) the outer boundary between West Berlin and its East German hinterland (see Table A2 of the web appendix for the coefficients on these distance grid cells).<sup>35</sup> Again we find a negative and statistically significant effect of proximity to the pre-war CBD that remains of around the same magnitude. In contrast, the coefficients for the inner boundary grid cells are close to zero and typically statistically insignificant, while the coefficients for the outer boundary grid cells are positive and statistically significant (although substantially smaller in magnitude than those for the pre-war CBD).<sup>36</sup>

Our finding that there is little evidence of a negative treatment effect of division along segments of the Berlin Wall far from the pre-war CBD suggests that our results are indeed capturing a loss of access to the pre-war CBD rather than other considerations associated with being close to the Berlin Wall such as its disamenity value. But by themselves these reduced-form regressions do not distinguish between different explanations for why access to the pre-war CBD matters, such as loss of access to employment opportunities, production externalities and/or residential externalities. In our structural estimation of the

---

<sup>34</sup>Table A1 in the web appendix reports the robustness test using standard errors clustered on statistical areas (“Gebiete”) instead of HAC standard errors following [Conley \(1999\)](#).

<sup>35</sup>The number of West Berlin blocks with floor price data in all three years in each grid cell for the inner boundary (from nearest to furthest from the inner boundary) are: 355, 406 431, 379, 313 and 326. The corresponding numbers for the outer boundary are 574, 646, 605, 594, 488 and 335. Comparing these numbers with those for the pre-war CBD grid cells in footnote 32, it is clear that the intersection of observations in each pair of grid cells is small relative to the union of observations in that pair of grid cells, which enables us to separately identify the coefficients for each grid cell.

<sup>36</sup>The small positive effects for the outer boundary could reflect a number of considerations. First, the areas beyond the outer boundary of Berlin are relatively undeveloped, implying little loss of access to surrounding economic activity following division. In 1933, total workplace and residence employment in Berlin were 1,628,622 and 1,591,723, respectively, implying small net inward commuting of 36,899. Second, there is a general equilibrium shift in economic activity within West Berlin following division. As a result, locations along the outer boundary of West Berlin become closer to the center of economic activity. Third, peak floor prices are lower relative to mean floor prices following division (compare Panels B and C of Figure 2). Since mean floor prices are constant by construction, this raises floor prices in peripheral locations relative to central locations. Fourth, there is the usual pattern of new residential developments appearing around the fringes of an existing city. Consistent with this, we below find positive effects along the outer boundary for residence employment but not workplace employment.

model below, we use the structure of the model to separate out these different explanations.

Column (4) shows that we find a similar pattern of results if we also include analogous 500 meter grid cells for distance to the Kudamm, providing further evidence that our results are indeed capturing a loss of access to the pre-war CBD (see Table A2 of the web appendix for the coefficients on these distance grid cells).<sup>37</sup> In Column (5), we further augment the specification from Column (4) with a wide range of controls for block characteristics. Although some of these controls are potentially endogenous to division, we demonstrate that our results are not driven by their omission by reporting results both with and without the controls. Our block characteristics include log distance to the nearest school in 2006, log distance to the nearest lake, river or canal in 2006, log distance to the nearest park in 2006, land use in 2006, log block area, Second World War destruction, and indicator variables for whether a block qualified for urban regeneration policies and government buildings post-reunification.<sup>38</sup>

In the next two Columns, we report results for employment residence. While Column (6) includes only our distance grid cells for proximity to the pre-war CBD and district fixed effects, Column (7) includes all the controls from Column (5). In both cases, we find that West Berlin blocks close to the pre-war CBD experienced a decline in employment residence relative to other parts of West Berlin following division. Columns (8) and (9) demonstrate a similar pattern of results for employment workplace.<sup>39</sup>

In Table 2, we report analogous specifications for reunification.<sup>40</sup> Consistent with the predictions of the model, we observe the reverse pattern of results for reunification. In Column (1), we include only the distance grid cells. We find that West Berlin blocks within the first distance grid cell experience around a 49 percent increase in the price of floor space between 1986 and 2006 ( $e^{0.398} - 1 = 0.49$ ) relative to those more than 3.75 kilometers away from the pre-war CBD. Together the six distance grid cells now explain around 8 percent of the observed variation in the change in the price of floor space ( $R^2 = 0.08$ ). Columns (2)-(5) show that these results are robust to including the same set of controls as for division (see Table A4 of the web appendix for the coefficients on the other distance grid cells). In Column (6)-(9), we report results for employment residence and employment workplace. Again we find statistically significant treatment effects, although these effects are less precisely estimated than for division.

---

<sup>37</sup>Division has several opposing effects on floor prices for locations close to the Kudamm. First, they lose access to the pre-war CBD to which they were relatively close. Second, the Kudamm becomes the new center of economic activity in West Berlin. Third, peak floor prices are lower relative to mean floor prices following division (compare Panels B and C of Figure 2). Since mean floor prices are constant by construction, this raises floor prices in peripheral locations relative to central locations. The net effect is small negative coefficients for the Kudamm distance grid cells.

<sup>38</sup>Our three indicator variables for urban regeneration programs are for whether a block qualified for “Sanierungsgebiet” in 2002, “Sanierungsgebiet” in 2006, and the “Stadtumbau West” program that was initiated in 2005.

<sup>39</sup>Although our identification strategy exploits relative changes across different parts of West Berlin, we also find that West Berlin’s overall population declines from 2,683,099 to 2,012,709 between the 1933 and 1987 censuses respectively, consistent with the predictions of the model discussed in subsection 3.8 above.

<sup>40</sup>Table A3 in the web appendix reports the robustness test using standard errors clustered on statistical areas (“Gebiete”) instead of HAC standard errors following Conley (1999).

### 5.3 Further Evidence

In Figure 3, we provide additional evidence on the timing of the estimated treatment effects, and demonstrate the absence of pre-trends. Panels A and B confirm our distance grid cell results by displaying the log difference in floor prices for each West Berlin block against distance from the pre-war CBD for 1936-86 and 1986-2006 respectively. We also show the locally-weighted linear least squares regression relationships between the two variables. From comparing Panels A and B, the effects of division are substantially larger and extend much further into West Berlin than the effects of reunification.

Panels C and D examine the timing of the division treatment by reporting results for 1936-66 and 1966-86 respectively. Consistent with the rapid disintegration of economic activity between West and East Berlin in the immediate aftermath of the Second World War, Panel C shows that most of the treatment effect of division on the price of floor space had already occurred by 1966. Therefore, as shown in Panel D, we find only a small negative treatment effect of division for 1966-86.<sup>41</sup> These results in Panel D also demonstrate that the positive treatment effect of reunification in Panel B is not driven by pre-trends in floor prices in the parts of West Berlin close to the pre-war CBD prior to reunification. Finally, Panel E displays results for 1928-36 and shows that the negative treatment effect of division is not driven by pre-trends in the parts of West Berlin close to the pre-war CBD prior to the Second World War.

In the web appendix, we provide further evidence that the estimated treatment effects of division and reunification are capturing a loss of access to the surrounding concentration of economic activity using a different source of variation in the data based on proximity to U/S-Bahn stations. Taken together, the results of this subsection provide further evidence in support of the model’s qualitative predictions of a reallocation of economic activity within West Berlin in response to both division and reunification.

## 6 Gravity, Productivity and Amenities

In this section, we take a first step towards examining the extent to which the model can account quantitatively for the observed variation in the data. In particular, we use the recursive structure of the model discussed in subsection 3.6 to recover overall productivity, amenities and the density of development just using the model’s gravity equation predictions for commuting flows. This approach has three advantages. First, we can determine the commuting parameters  $\{\epsilon, \kappa\}$  using only information on commuting probabilities and wages and without taking a stand on the values of the agglomeration parameters  $\{\lambda, \delta, \eta, \rho\}$ . Hence we can solve for overall adjusted productivity, amenities and the density of development  $\{\tilde{A}_i, \tilde{B}_i, \tilde{\varphi}_i\}$  regardless of the relative importance or functional form of externalities  $\{\Upsilon_{it}, \Omega_{it}\}$  and fundamentals  $\{\tilde{a}_{it}, \tilde{b}_{it}\}$ . Second, we can determine the commuting parameters  $\{\epsilon, \kappa\}$  without imposing the full set of identifying assumptions used in the structural estimation in section 7 below, which thus provides an overidentification check on the model’s predictions. Third, we use the solutions for overall adjusted productivity, amenities

---

<sup>41</sup>Tables A.5-A.8 corroborate these findings by re-estimating the “difference-in-difference” regression specifications in Table 1. While the division treatment is large and statistically significant for 1936-66 in Tables A.5-A.6, it is small and typically statistically insignificant for 1966-86 in Tables A.7-A.8.

and the density of development  $\{\tilde{A}_i, \tilde{B}_i, \tilde{\varphi}_i\}$  to show that the model with exogenous location characteristics is unable to explain the observed impact of division and reunification.

## 6.1 Gravity

One of the model's key predictions is a gravity equation for commuting flows. From (4), this gravity equation has a semi-log functional form, in which the log of the bilateral commuting probability ( $\ln \pi_{ij}$ ) from residence  $i$  to workplace  $j$  depends on travel times ( $\tau_{ij}$ ), residence fixed effects ( $\vartheta_i$ ) and workplace fixed effects ( $\varsigma_j$ ):

$$\ln \pi_{ij} = -\nu \tau_{ij} + \vartheta_i + \varsigma_j + e_{ij}, \quad (23)$$

where the semi-elasticity of commuting flows with respect to travel times  $\nu = \epsilon\kappa$  is a combination of the commuting cost parameter  $\kappa$  and the commuting heterogeneity parameter  $\epsilon$ ; travel times  $\tau_{ij}$  are measured in minutes; and  $e_{ij}$  is a stochastic shock to bilateral commuting costs.

To provide empirical evidence on these gravity equation predictions, we estimate (23) using micro data on a representative survey of individual commuters in Berlin for 2008, which report district of residence, district of workplace and bilateral travel times in minutes for 7,948 commuters. We use these micro survey data to compute the probability that a worker commutes between any of the 12 districts of Berlin in 2008, which yields  $12 \times 12 = 144$  pairs of bilateral commuting probabilities.<sup>42</sup> We observe positive commuting probabilities for all bilateral district pairs, although some district pairs have a small number of commuters in these micro survey data. In Column (1) of Table 3, we estimate (23) using a linear fixed effects estimator, and find a semi-elasticity of commuting with respect to travel time of -0.0697 that is statistically significant at the one percent level. This estimate implies that each additional minute of travel time reduces the flow of commuters by around 0.07 percent. From the regression R-squared, this gravity equation specification explains around 83 percent of the variation in bilateral commuting patterns. To address concerns about sampling error for bilateral pairs with small numbers of commuters in these micro survey data, Column (2) re-estimates the same specification restricting attention to bilateral pairs with 10 or more commuters. We find a semi-elasticity of a similar magnitude of -0.0702, which is now more precisely estimated, and the regression R-squared rises to 91 percent.

The remaining two columns of Table 3 report additional robustness checks suggested by the international trade literature on gravity equations (see in particular [Head and Mayer 2014](#)). In Column (3), we estimate the fixed effects specification from Column (2) using a Poisson Pseudo Maximum Likelihood estimator, and find a semi-elasticity of -0.0771. In Column (4), we re-estimate the same specification using a Gamma Pseudo Maximum Likelihood estimator, and find a semi-elasticity of -0.0723. Therefore, across a range of different specifications, we find a precisely estimated value of  $\nu = \epsilon\kappa$  of around 0.07. Taken together, these results suggest that the gravity equation predicted by the model provides a good approximation to observed commuting behavior.

In Panel A of Figure 4, we provide further evidence on the fit of the semi-elasticity functional form

---

<sup>42</sup>The districts reported in the micro survey data are post-2001 districts, as discussed in footnote 8.

implied by the model using the specification from Column (2) of Table 3. We regress both the log bilateral commuting probabilities and travel times on workplace and residence fixed effects and graph the residuals from these two regressions against one another. As apparent from the figure, the semi-elasticity functional form provides a good fit to the data, with an approximately linear relationship between the two residuals.<sup>43</sup>

Using our estimate for  $\nu = \epsilon\kappa = 0.07$  from the gravity equation estimation, the model's labor market clearing condition (7) can be solved for a transformation of wages ( $\omega_{it}$ ) in each location in each year using observed workplace employment ( $H_{Mjt}$ ), residence employment ( $H_{Rit}$ ) and bilateral travel times ( $\tau_{ijt}$ ):

$$H_{Mjt} = \sum_{i=1}^S \frac{\omega_{jt}/e^{\nu\tau_{ijt}}}{\sum_{s=1}^S \omega_{st}/e^{\nu\tau_{ijt}}} H_{Rit}, \quad (24)$$

where transformed wages ( $\omega_{it}$ ) depend on adjusted wages ( $\tilde{w}_{jt}$ ) and the Fréchet shape parameter ( $\epsilon$ ) determining the heterogeneity in workers' commuting choices:  $\omega_{jt} = \tilde{w}_{jt}^\epsilon = E_{jt} w_{jt}^\epsilon$ . Given these solutions for transformed wages from the labor market clearing condition, the model yields predictions for bilateral commuting flows (using (6)).

To compare the model's predictions to the micro survey data, we aggregate the bilateral commuting flows between blocks in the model to construct bilateral commuting probabilities between districts. In Panel B of Figure 4, we display log commuting probabilities between districts in the model and micro survey data. Again we focus on the sample of bilateral pairs with 10 or more commuters in the micro survey data. Although the gravity equation (23) holds exactly in the model, it does not fit the micro survey data perfectly for two reasons. First, the R-squared of the reduced-form gravity equation (23) is not 100 percent. Second, the bilateral travel times in the model are estimated based on minimum travel time calculations using the transport network and need not equal the self-reported travel times in the micro survey data.

We now undertake a number of further overidentification checks on the model's commuting predictions. Given our estimate for  $\nu = \epsilon\kappa = 0.07$  from the gravity equation estimation for 2008, we use the model to predict commuting flows and construct a cumulative distribution function of commuters across travel time bins (for example, 20-30 minutes) for all three years of our sample. We compare these predictions of the model to the corresponding cumulative distribution functions in the data. For reunification, we use the micro survey data for individual commuters for 2008 used in the gravity equation estimation above. For division, we use separate data on the fractions of workers in discrete travel time bins from a representative sample of commuters in West Berlin in 1982. For the pre-war period, we use the data reported in Feder (1939).

In Panel C of Figure 4, we show the cumulative distribution functions of commuters across the travel time bins in the model and micro survey data for Berlin in 2008. Although these moments were not used in the gravity equation estimation of  $\nu = \epsilon\kappa$  above, we find that the model approximates the cumulative

---

<sup>43</sup>The use of reduced-form gravity equations for commuting flows has a long tradition in urban and regional economics, as reviewed in McDonald and McMillen (2010). Fortheringham and O'Kelly (1989) argue that the consensus in the literature is that a semi-log specification provides the best fit to commuting data within cities. A recent contribution to this literature using a semi-log specification and travel times is McArthur, Kleppe, Thorsen, and Uboe (2011), which finds a similar semi-elasticity of commuting flows with respect to travel times as we find for Berlin.

distribution function in the data well. In Panel D of Figure 4, we undertake the same exercise for West Berlin in 1986. Although the smaller geographic area of West Berlin ensures that it has a quite different distribution of workplace employment, residence employment and travel times from Berlin, we again find that the model approximates the relationship in the data. Finally, in Panel E of Figure 4, we repeat the exercise for Berlin in 1936. Although the distribution of travel times for Berlin differs between 1936 (based on public transport) and 2006 (based on public transport and private cars), we again find that the model has explanatory power for the data.<sup>44</sup>

Therefore, despite our model necessarily being an abstraction, we find that it is successful in capturing the key features of commuting patterns in Berlin during our sample period, and successfully predicts moments not used in the estimation of the commuting parameters.

## 6.2 Productivity and Amenities

We now use the gravity equation estimation to recover overall adjusted productivity, amenities and the density of development  $\{\tilde{A}_{it}, \tilde{B}_{it}, \tilde{\varphi}_i\}$ . We use the model to recover these objects without taking a stand of the relative importance of externalities and fundamentals. From profit maximization and zero profits (12), log adjusted final goods productivity relative to its geometric mean is:

$$\ln \left( \frac{\tilde{A}_{it}}{\bar{\tilde{A}}_t} \right) = (1 - \alpha) \ln \left( \frac{Q_{it}}{\bar{Q}_t} \right) + \frac{\alpha}{\epsilon} \ln \left( \frac{\omega_{it}}{\bar{\omega}_t} \right), \quad (25)$$

where a bar above a variable denotes a geometric mean so that  $\bar{\tilde{A}}_t = \exp\{\frac{1}{S} \sum_{s=1}^S \ln \tilde{A}_{st}\}$ . Intuitively high floor prices and wages in (25) require high final goods productivity in order for zero profits to be satisfied.

From the residential choice probabilities (5) and population mobility with the larger economy (9), log residential amenities relative to their geometric mean are:

$$\ln \left( \frac{\tilde{B}_{it}}{\bar{\tilde{B}}_t} \right) = \frac{1}{\epsilon} \ln \left( \frac{H_{Rit}}{\bar{H}_{Rt}} \right) + (1 - \beta) \ln \left( \frac{Q_{it}}{\bar{Q}_t} \right) - \frac{1}{\epsilon} \ln \left( \frac{W_{it}}{\bar{W}_t} \right), \quad (26)$$

where  $W_{it}$  is a measure of commuting market access that can be written in terms of the transformed wages ( $\omega_{it}$ ) from the gravity equation estimation:

$$W_{it} = \sum_{s=1}^S \omega_{st} / e^{\epsilon \kappa \tau_{ist}}, \quad \omega_{st} = \tilde{w}_{st}^\epsilon = E_{st} w_{st}^\epsilon. \quad (27)$$

Intuitively, high residence employment and high floor prices in (26) must be explained either by high commuting market access or attractive residential amenities.

Using residential land market clearing (17) and commercial land market clearing (18), we can also recover the adjusted density of development relative to its geometric mean. To solve for adjusted productivity, amenities and the density of development, we require values for a subset of the model's parameters:  $\{\alpha, \beta,$

<sup>44</sup>Consistent with the results in [Duranton and Turner \(2011\)](#) for U.S. metropolitan areas, we find that the majority of commuters in Berlin have travel times of less than forty-five minutes in all three years of our sample.

$\mu, \epsilon, \kappa$ }. Of these parameters, the share of residential floor space in consumer expenditure ( $1 - \beta$ ), the share of commercial floor space in firm costs ( $1 - \alpha$ ), and the share of land in construction costs ( $1 - \mu$ ) are hard to determine from our data, because information on consumer expenditures and factor payments at the block level is not available over our long historical sample period. As there is a degree of consensus about the value of these parameters, we set them equal to central estimates from the existing empirical literature. We set the share of consumer expenditure on residential floor space ( $1 - \beta$ ) equal to 0.25, which is consistent with the estimates in [Davis and Ortalo-Magné \(2011\)](#). We assume that the share of firm expenditure on commercial floor space ( $1 - \alpha$ ) is 0.20, which is in line with the findings of [Valentinyi and Herrendorf \(2008\)](#). We set the share of land in construction costs ( $1 - \mu$ ) equal to 0.25, which is consistent with the estimates in [Combes, Duranton, and Gobillon \(2014\)](#) and [Epple, Gordon, and Sieg \(2010\)](#) and with micro data on property transactions that is available for Berlin from 2000-2012, as discussed in the web appendix.

We use our estimate of  $\nu = \epsilon\kappa = 0.07$  from the gravity equation estimation above. Therefore, to recover adjusted productivity, amenities and the density of development  $\{\tilde{A}_{it}, \tilde{B}_{it}, \tilde{\varphi}_{it}\}$ , the only remaining parameter that has to be determined is the Fréchet shape parameter ( $\epsilon$ ) capturing the heterogeneity in workers' commuting decisions. From the labor market clearing condition (24), transformed wages ( $\omega_{it}$ ) are determined independently of  $\epsilon$  from workplace employment, residence employment and travel times. The parameter  $\epsilon$  only determines the monotonic transformation that maps transformed wages ( $\omega_{it}$ ) into adjusted wages ( $\tilde{w}_{it} = \omega_{it}^{1/\epsilon}$ ). Therefore  $\epsilon$  merely scales the dispersion of log adjusted wages relative to the dispersion of log transformed wages:  $\sigma_{\ln \tilde{w}_{it}}^2 = (1/\epsilon)^2 \sigma_{\ln \omega_{it}}^2$ . To calibrate the value of the Fréchet shape parameter ( $\epsilon$ ), we use data on the dispersion of log wages across the districts of West Berlin for 1986. We choose  $\epsilon$  to minimize the squared difference between the variance of log wages across districts in the model and data, which yields a value of  $\epsilon = 6.83$ .<sup>45</sup> This value of  $\epsilon = 6.83$  for commuting patterns is broadly in line with the range of estimates for the Fréchet shape parameter for international trade flows (the range of estimates in [Eaton and Kortum \(2002\)](#) is from 3.60 to 12.86 with a preferred value of 8.28).

From  $\nu = \epsilon\kappa = 0.07$  and  $\epsilon = 6.83$ , we obtain  $\kappa = 0.01$ . Using these parameter values, we solve the labor market clearing condition (24) for transformed wages ( $\omega_{it}$ ), the zero profit condition (25) for adjusted productivity ( $\tilde{A}_{it}$ ) and the residential choice condition (26) for adjusted amenities ( $\tilde{B}_{it}$ ) in each year of our sample. We treat these solutions of the model as data and examine the changes in productivity and amenities underlying the impact of division and reunification in our reduced-form “difference-in-difference” specification (22).

In Column (1) of Table 4, we estimate our baseline specification for the impact of division for adjusted productivity ( $\tilde{A}_i$ ) including our six grid cells for distance to the pre-war CBD. We find substantial and statistically significant negative treatment effects of division. For example, for the first distance grid cell, we estimate a reduction in productivity of -0.207 log points. In Column (2), we estimate the same specification for adjusted amenities ( $\tilde{B}_i$ ). Again we find substantial and statistically significant negative treatment effects

<sup>45</sup>Wages across West Berlin districts in 1986 differ by a maximum value of 26 percent, which is in line with the maximum difference in mean residual wages (after controlling for worker observables) across areas of Boston and Minneapolis of 15 and 18 percent reported in [Timothy and Wheaton \(2001\)](#).

of division. For example, for the first distance grid cell, we estimate a reduction in amenities of -0.347 log points. Columns (3) and (4) demonstrate a similar pattern of results for reunification, although the estimated effects are smaller and more localized. These results provide a first piece of evidence that a model in which productivity and amenities are exogenous and unaffected by division and reunification is going to be hard to reconcile with the data.

### 6.3 Counterfactuals

To provide further evidence on the ability of a model with exogenous productivity, amenities and the density of development to explain the data, we now undertake counterfactuals for the effects of division and reunification for this special case of the model. Even with exogenous location characteristics, the model predicts treatment effects from division and reunification. Residents in the areas of West Berlin close to the pre-war CBD lose access to nearby employment opportunities in East Berlin, and firms in these areas lose access to nearby sources of commuters from East Berlin. As shown in Proposition 1, the model has a unique equilibrium in this special case of exogenous location characteristics. Therefore these counterfactuals yield determinate predictions for the impact of division and reunification.

In our first counterfactual, we simulate the impact of division on West Berlin, holding productivity, amenities and density of development constant at their 1936 values. In Column (5) of Table 4, we re-estimate our baseline “difference-in-difference” specification using the counterfactual changes in floor prices predicted by the model with exogenous location characteristics instead of the actual changes in floor prices. We find that the counterfactual treatment effect of division is negative and statistically significant, but much smaller than the actual treatment effect of division (-0.229 log points as compared to -0.800 log points for the first distance grid cell in Column (1) of Table 1).

In our second counterfactual, we simulate the impact of reunification on West Berlin, holding productivity, amenities and the density of development constant at their 1986 values in West Berlin, and using the 2006 values of these location characteristics for East Berlin. In Column (6) of Table 4, we re-estimate our baseline “difference-in-difference” specification for the impact of reunification using the counterfactual changes in floor prices. We find that the counterfactual treatment effect of reunification is positive and statistically significant, but again smaller than the actual treatment effect of reunification (0.065 log points as compared to 0.398 log points for the first distance grid cell in Column (1) of Table 2).

The results of these counterfactuals provide further evidence that a model in which productivity and amenities are exogenous and unaffected by division and reunification is unable to explain the data.

## 7 Structural Estimation

In the previous section, we used the model’s gravity equation predictions to determine the commuting parameters  $\{\nu, \epsilon\}$  without taking a stand on the agglomeration parameters  $\{\lambda, \delta, \eta, \rho\}$ . In this section, we use the exogenous variation from Berlin’s division and reunification to structurally estimate the model’s full set of parameters for agglomeration and dispersion forces  $\{\nu, \epsilon, \lambda, \delta, \eta, \rho\}$ , where  $\nu = \epsilon\kappa$ . This enables us

to decompose productivity and amenities  $\{\tilde{A}_i, \tilde{B}_i\}$  into their two components of externalities  $\{\Upsilon_i, \Omega_i\}$  and adjusted fundamentals  $\{\tilde{a}_i, \tilde{b}_i\}$ . We continue to assume the same central values for the share of floor space in consumer expenditure  $(1 - \beta)$ , the share of floor space in firm costs  $(1 - \alpha)$ , and the share of land in construction costs  $(1 - \mu)$  as in section 6.2 above.

First, we show that adjusted production and residential fundamentals  $\{\tilde{a}_{it}, \tilde{b}_{it}\}$  are structural residuals of the model that are one-to-one functions of the observed data and parameters. Second, we develop moment conditions in terms of these structural residuals that use the exogenous variation induced by Berlin's division and reunification. Third, we discuss the Generalized Method of Moments (GMM) estimation. Fourth, we show how the moment conditions identify the model's parameters. Fifth, we report the GMM estimation results and discuss a robustness check in which we constrain the values of  $\nu$  and  $\epsilon$  to equal the values found in our gravity equation estimation in the previous section. Sixth, we compare our results to findings from the existing literature. Seventh, we report additional over identification checks on the model's predictions. Finally, we use the estimated model to undertake a number of additional counterfactuals for the effects of division and reunification.

## 7.1 Structural Residuals

In this section, we use the results from Proposition 2 to express adjusted production and residential fundamentals in terms of the observed data and parameters. From profit maximization and zero profits (12) and productivity (20), the proportional change in adjusted production fundamentals in each block relative to the geometric mean can be written as the following function of observed variables and parameters:

$$\Delta \ln \left( \frac{\tilde{a}_{it}}{\bar{a}_t} \right) = (1 - \alpha) \Delta \ln \left( \frac{Q_{it}}{Q_t} \right) + \frac{\alpha}{\epsilon} \Delta \ln \left( \frac{\omega_{it}}{\bar{\omega}_t} \right) - \lambda \Delta \ln \left( \frac{\Upsilon_{it}}{\bar{\Upsilon}_t} \right), \quad (28)$$

where production externalities  $\{\Upsilon_{it}\}$  depend on the travel-time weighted sum of observed workplace employment densities (from (20));  $\omega_{it}$  can be solved from observed workplace employment and residence employment from labor market clearing (24), as discussed in section 6.1; and a bar above a variable denotes a geometric mean such that  $\bar{a}_t = \exp \left\{ \frac{1}{S} \sum_{s=1}^S \ln \tilde{a}_{it} \right\}$ .

From population mobility and utility maximization (5) and amenities (21), the proportional change in adjusted residential fundamentals in each block relative to the geometric mean can be written as the following function of observed variables and parameters:

$$\Delta \ln \left( \frac{\tilde{b}_{it}}{\bar{b}_t} \right) = \frac{1}{\epsilon} \Delta \ln \left( \frac{H_{Rit}}{H_{Rt}} \right) + (1 - \beta) \Delta \ln \left( \frac{Q_{it}}{Q_t} \right) - \frac{1}{\epsilon} \Delta \ln \left( \frac{W_{it}}{\bar{W}_t} \right) - \eta \Delta \ln \left( \frac{\Omega_{it}}{\bar{\Omega}_t} \right), \quad (29)$$

where residential externalities  $\{\Omega_{it}\}$  depend on the travel-time weighted sum of observed residence employment densities (from (21)); commuting market access  $\{W_{it}\}$  can be solved from observed workplace employment and residence employment (using labor market clearing (24) and (27)); and a bar above a variable again denotes a geometric mean.

The structural residuals in (28) and (29) difference out any time-invariant fixed effect in adjusted production and residential fundamentals for each block (e.g. access to natural water), because of the differencing

before and after division (as denoted by the time-difference operator  $\Delta$ ). These structural residuals also difference out any common fixed effect across all blocks in each year (e.g. changes in the reservation level of utility  $\bar{U}_t$  or the choice of units in which to measure production and residential fundamentals), because we divide by the geometric mean of each variable in each year before taking logs. Therefore the mean changes in log adjusted production and residential fundamentals in (28) and (29) are necessarily equal to zero.

## 7.2 Moment Conditions

Our first set of moment conditions impose that the changes in the structural residuals for adjusted production and residential fundamentals in (28) and (29) are uncorrelated with the exogenous change in the surrounding concentration of economic activity induced by Berlin's division and reunification. Based on the results of our reduced-form regressions, we capture this exogenous change in the surrounding concentration of economic activity using distance grid cells from the pre-war CBD. Therefore our first set of moment conditions take the following form:

$$\mathbb{E} \left[ \mathbb{I}_k \times \Delta \ln \left( \tilde{a}_{it} / \bar{a}_t \right) \right] = 0, \quad k \in \{1, \dots, K_{\mathbb{I}}\}, \quad (30)$$

$$\mathbb{E} \left[ \mathbb{I}_k \times \Delta \ln \left( \tilde{b}_{it} / \bar{b}_t \right) \right] = 0, \quad k \in \{1, \dots, K_{\mathbb{I}}\}. \quad (31)$$

where  $\mathbb{I}_k$  for  $k \in \{1, \dots, K_{\mathbb{I}}\}$  are indicator variables for distance grid cell  $k$  from the pre-war CBD. We use 50 indicator variables based on percentiles of distance to the pre-war CBD. Therefore the moment conditions (30) and (31) impose that the mean change in log adjusted production and residential fundamentals is zero for each of the distance grid cells.

This identifying assumption requires that the systematic change in the gradient of economic activity in West Berlin relative to the pre-war CBD following division is explained by the mechanisms in the model (the changes in commuting access and production and residential externalities) rather than by systematic changes in the pattern of structural residuals (adjusted production and residential fundamentals).<sup>46</sup> Since Berlin's division stemmed from military considerations during the Second World War and its reunification originated in the wider collapse of Communism, the resulting changes in the surrounding concentration of economic activity are plausibly exogenous to changes in adjusted production and residential fundamentals in West Berlin blocks.

In addition to the above moment conditions for adjusted production and residential fundamentals, we use two other moment conditions for division and reunification based on commuting travel times and wage dispersion for West Berlin during division.<sup>47</sup> The first of these moment conditions requires that the total number of workers commuting for less than 30 minutes in the model is equal to the corresponding number

<sup>46</sup>We do not use moment conditions in the adjusted density of development ( $\tilde{\varphi}_i$ ) in our estimation, because the density of development could in principle respond to changes in the relative demand for land across locations within West Berlin as a result of the mechanisms in the model (the changes in commuting access and production and residential externalities).

<sup>47</sup>In section 6.1, we reported over identification checks in which we showed that the model using an estimated value of  $\nu = \epsilon\kappa$  for one year is successful in capturing the pattern of commuting flows in other years of the data, suggesting that the commuting parameters are stable over our sample period.

in the data. From the commuting market clearing condition (24), this moment condition can be expressed as the following expectation:

$$\mathbb{E} \left[ \vartheta H_{Mj} - \sum_{i \in \aleph_j} \frac{\omega_j / e^{\nu \tau_{ij}}}{\sum_{s=1}^S \omega_s / e^{\nu \tau_{is}}} H_{Ri} \right] = 0, \quad (32)$$

where  $\vartheta$  in the first term inside the square parentheses is the fraction of workers that commute for less than 30 minutes in the data;  $\aleph_j$  is set of residence locations  $i$  within 30 minutes travel time of workplace location  $j$ ; hence the second term inside the square parentheses captures the model's predictions for commuting flows with travel times less than 30 minutes.

The second of these moment conditions requires that the variance of log adjusted wages in the model ( $\text{var}(\tilde{w}_i)$ ) is equal to the variance of wages in the data ( $\sigma_{\ln w_i}^2$ ) for West Berlin during division.<sup>48</sup>

$$\mathbb{E} \left[ (1/\epsilon)^2 \ln(\omega_j)^2 - \sigma_{\ln w_i}^2 \right] = 0, \quad (33)$$

where transformed wages ( $\omega_i$ ) depend solely on  $\nu$ , workplace employment, residence employment and travel times from the labor market clearing condition (24); we normalize transformed wages so that the mean of log transformed wages is zero. The parameter  $\epsilon$  scales the variance of log adjusted wages ( $\tilde{w}_i$ ) relative to the variance of log transformed wages ( $\omega_i$ ).

### 7.3 GMM Estimation

We use the above moment conditions and the Generalized Method of Moments (GMM) to estimate the model's full set of parameters for agglomeration and dispersion forces  $\Lambda = \{\nu, \epsilon, \lambda, \delta, \eta, \rho\}$ . Stacking our moment conditions together, we obtain:

$$\mathbb{M}(\Lambda) = \frac{1}{N} \sum_{i=1}^N m(\mathbf{X}_i, \Lambda) = 0. \quad (34)$$

where  $m(\mathbf{X}_i, \Lambda)$  is the moment function for observation  $i$ .

We estimate the model separately for the difference between the pre-war and division periods and for the difference between the division and reunification periods. The efficient GMM estimator solves:

$$\hat{\Lambda}_{\text{GMM}} = \arg \min \left( \frac{1}{N} \sum_{i=1}^N m(\mathbf{X}_i, \Lambda)' \right) \mathbb{W} \left( \frac{1}{N} \sum_{i=1}^N m(\mathbf{X}_i, \Lambda) \right) \quad (35)$$

where  $\mathbb{W}$  is the efficient weighting matrix. As in our reduced-form estimation, we report Heteroscedasticity and Autocorrelation Consistent (HAC) standard errors that allow for spatial correlation in the errors following Conley (1999).

This minimization problem involves evaluating the moment conditions (34) for each parameter vector and searching over alternative parameter vectors ( $\Lambda$ ). We briefly discuss here the algorithms that we use

<sup>48</sup>As reliable wage data for pre-war Berlin is unavailable, we use wages by workplace for West Berlin during division in our moment conditions, which is consistent with our use of the commuting data above.

to solve these problems and include a more detailed discussion in the web appendix. First, evaluating the moment conditions for each parameter vector involves solving a fixed point problem for the vector of transformed wages that solves the commuting market clearing condition (7). In the web appendix, we show analytically that transformed wages are gross substitutes in the commuting market clearing condition and that this system of equations has a unique solution (see Lemmas A6 and A7). Therefore, we solve for transformed wages using an iterative fixed point procedure that converges rapidly to this unique solution. Second, this iterative fixed point problem is nested within an optimization routine over the parameter vector ( $\Lambda$ ). We use standard optimization algorithms to search over alternative possible values for the parameter vector.

## 7.4 Identification

We now discuss how the moment conditions identify the parameters  $\Lambda = \{\nu, \epsilon, \lambda, \delta, \eta, \rho\}$ . We begin with the semi-elasticity of commuting flows with respect to travel times ( $\nu$ ). From the commuting market clearing condition (24), bilateral commuting flows depend solely on the parameter  $\nu$ , transformed wages  $\omega_{it}$  and observed workplace employment, residence employment and travel times. A higher value of  $\nu$  implies that commuting flows decline more rapidly with travel times, which implies that a larger fraction of workers commute for less than thirty minutes in the commuting moment condition (32). The recursive structure of the model implies that none of the other parameters  $\{\epsilon, \lambda, \delta, \eta, \rho\}$  affect the commuting moment condition ( $\epsilon$  only enters through  $\nu = \epsilon\kappa$ ).

We next consider the Fréchet shape parameter determining the heterogeneity of workers' commuting decisions ( $\epsilon$ ). A higher value of  $\epsilon$  implies a smaller dispersion in adjusted wages ( $\tilde{w}_{it}$ ) in the wage moment condition (33) for a given dispersion of transformed wages ( $\omega_{it}$ ), since  $\sigma_{\ln \tilde{w}_{it}}^2 = (1/\epsilon)^2 \sigma_{\ln \omega_{it}}^2$ . From the commuting market clearing condition (24), transformed wages ( $\omega_{it}$ ) depend solely on the parameter  $\nu$  and observed workplace employment, residence employment and travel times. The recursive structure of the model implies that none of the other parameters  $\{\lambda, \delta, \eta, \rho\}$  affect the wage moment condition.

We now turn to the production parameters  $\{\lambda, \delta\}$ , which only enter the moment condition (30) for adjusted production fundamentals, and do not affect any of the other moment conditions (since these parameters merely decompose  $\tilde{A}_{it}$  into its components). In the data, we observe a decline in floor prices ( $Q_{it}$ ) in the areas of West Berlin close to the Berlin Wall. From profit maximization and zero profits (25), these falls in floor prices together with the change in wages ( $w_{it}$ ) determine the change in adjusted overall productivity ( $\tilde{A}_{it}$ ), which includes both production externalities ( $\Upsilon_{it}$ ) and adjusted production fundamentals ( $\tilde{a}_{it}$ ).

The division of Berlin implies a reduction of production externalities ( $\Upsilon_{it}$ ) for the parts of West Berlin close to the Berlin Wall. If this reduction in production externalities does not fully explain the change in adjusted productivity ( $\tilde{A}_{it}$ ) close to the Berlin Wall, the remainder will be explained by a change in adjusted production fundamentals ( $\tilde{a}_{it}$ ). From the moment condition (30), the production parameters  $\{\lambda, \delta\}$  are chosen to make the mean changes in log adjusted production fundamentals (28) as flat as possible across the distance grid cells from the pre-war CBD. The parameter  $\lambda$  determines the overall impact of the lost production externalities on productivity, while the parameter  $\delta$  determines the spatial decay of the lost

production externalities with travel time from the pre-war CBD.

Finally, we consider the residential parameters  $\{\eta, \rho\}$ , which only enter the moment condition (31) for adjusted residential fundamentals, and do not affect any of the other moment conditions (since these parameters merely decompose  $\tilde{B}_{it}$  into its components). In the data, we observe a decline in floor prices ( $Q_{it}$ ) and residence employment ( $H_{Ri}$ ) close to the pre-war CBD. Furthermore, the model implies a decline in commuting market access ( $W_{it}$ ) close to the pre-war CBD, because of the loss of access to employment opportunities in East Berlin. To the extent that the fall in residence employment is not completely explained by these changes in floor prices and commuting market access, the remainder will be explained by a reduction in adjusted amenities ( $\tilde{B}_{it}$ ), which include residential externalities ( $\Omega_{it}$ ) and adjusted residential fundamentals ( $\tilde{b}_{it}$ ).

The division of Berlin implies a reduction of residential externalities ( $\Omega_{it}$ ) for the parts of West Berlin close to the Berlin Wall. If this reduction in residential externalities does not fully explain the reduction in adjusted amenities ( $\tilde{B}_{it}$ ) close to the Berlin Wall, the remainder will be explained by a change in adjusted residential fundamentals ( $\tilde{b}_{it}$ ). From the moment condition (31), the residential parameters  $\{\eta, \rho\}$  are chosen to make the mean changes in log adjusted residential fundamentals (29) as flat as possible across the distance grid cells from the pre-war CBD. The parameter  $\eta$  determines the overall impact of the lost residential externalities on amenities, while the parameter  $\rho$  determines the spatial decay of the lost residential externalities with travel time from the pre-war CBD.

Intuitively, production and residential externalities are separately identified from one another, because production externalities are inferred from firm choices about production, while residential externalities are inferred from worker choices of residence. In particular, overall productivity ( $A_{it}$ ) is obtained from profit maximization and zero profits, and productivity is separated into externalities ( $\Upsilon_{it}$ ) and fundamentals ( $a_{it}$ ) using the surrounding density of workplace employment. In contrast, overall amenities ( $B_{it}$ ) are obtained from utility maximization and population mobility, and amenities are separated into externalities ( $\Omega_{it}$ ) and fundamentals ( $b_{it}$ ) using the surrounding density of residence employment.

In subsection A4.5 of the web appendix, we undertake a grid search over the parameter space and show that the GMM objective is well-behaved in the parameter space with a unique global minimum that identifies the parameters. In section A6 of the web appendix, we report the results of a Monte Carlo simulation, in which we generate data for a hypothetical city using known parameters, and show that our estimation approach recovers the correct values of these known parameters.

## 7.5 GMM Estimation Results

In Table 5, we report efficient GMM estimation results for the division and reunification experiments, both separately and pooling the two experiments. In Column (1), we report the results for division. We find evidence of substantial and statistically significant agglomeration forces, with an estimated elasticity of productivity with respect to the surrounding concentration of workplace employment of  $\lambda = 0.07$ , and an estimated elasticity of amenities with respect to the surrounding concentration of residence employment of  $\eta = 0.14$ . Both production and residential externalities are highly localized, with exponential rates of

decay of  $\delta = 0.36$  and  $\rho = 0.89$  respectively.

We find similar commuting parameters as in our earlier estimation based on the gravity equation, with a semi-elasticity of commuting flows with respect to travel time of  $\nu = \epsilon\kappa = 0.10$  compared to  $\nu = 0.07$ . These estimates are similar despite using quite different moments in the data. Whereas our gravity estimate is based on bilateral commuting flows controlling for residence and workplace fixed effects, our structural estimates here are based on the cumulative distribution function of commuters across travel times. We also estimate a similar value for the Fréchet shape parameter determining heterogeneity in commuting decisions as in our earlier calibration ( $\epsilon = 7.63$  versus  $\epsilon = 6.83$ ). Here the difference in estimates reflects the fact that  $\epsilon$  also affects the moment conditions for double-differenced production and residential fundamentals used in our structural estimation. Together our estimates of  $\nu$  and  $\epsilon$  imply a spatial decay parameter for commuting costs of  $\kappa = \nu/\epsilon = 0.01$ .

In Column (2) of Table 5, we report the efficient GMM estimation results for reunification. We find a broadly similar pattern of results, although the estimates are smaller and less precisely estimated for reunification, which is in line with our earlier reduced-form findings that reunification is a much smaller and more localized shock than division (see Figure 3). We find an elasticity of productivity with respect to production externalities of  $\lambda = 0.04$  and an elasticity of amenities with respect to residential externalities of  $\eta = 0.07$ , which are both significant at conventional levels. Production and residential externalities are again highly localized with rates of spatial decay of 0.89 and 0.55 respectively (although the spatial decay of residential externalities is not significant at conventional levels). Our estimates of both commuting parameters are again similar to our earlier estimates based on the gravity equation.

In Column (3) of Table 5, we report the efficient GMM results pooling the division and reunification experiments. We again find a similar pattern of results. The estimated coefficients are closer to the results for division than those for reunification, which again reflects the fact that division is a much larger experiment. To illustrate the magnitude of the spatial decays implied by our parameter estimates, Columns (1) and (2) of Table 6 report the proportional reductions in production and residential externalities with travel time, using the pooled efficient GMM parameter estimates. After around 10 minutes of travel time, both production and residential externalities fall to close to zero. Given our estimated travel speeds for each mode of transport, 10 minutes of travel time corresponds to around 0.83 kilometers by foot (at an average speed of five kilometers per hour) and about 4 kilometers by U-Bahn or S-Bahn (at an average speed of 25 kilometers per hour).

In Column (3) of Table 6, we report the proportional increase in commuting costs with travel time, again using the pooled efficient GMM parameter estimates. Commuting costs are much less responsive to travel times than production or residential externalities. Nonetheless, consistent with the rapid observed decline in commuting with travel time, the implied commuting costs are still substantial. Other things equal, after around 10 minutes of travel time, utility falls by 12 percentage points ( $(1 - 0.88) \times 100$ ). In interpreting this result, one has to take into account that workers self-select across bilateral commutes. Intuitively, workers will only choose to take an extremely long bilateral commute if they have a high draw for the idiosyncratic utility derived from that pair of workplace and residence locations. More formally, an implication of the Fréchet distribution for idiosyncratic utility is that average utility conditional on choosing

a bilateral commute is the same for all bilateral commutes, as shown in section A.2.3 in the web appendix.

To provide evidence on the fit of the estimated model, we examine the extent to which the changes in productivity and amenities at different distances from the pre-war CBD are explained by the economic mechanisms in the model (changes in commuting access and production and residential externalities) rather than by the structural residuals (production and residential fundamentals). In particular, we treat the solutions of the model as data and estimate our reduced-form “difference-in-difference” specification (22). As reported in Table A.12 of the web appendix, we find substantial and statistically significant treatment effects of division and reunification for overall productivity and amenities  $\{A_i, B_i\}$  (as in subsection 6.3) and for production and residential externalities  $\{\Upsilon_i^\lambda, \Omega_i^\eta\}$ . In contrast, the estimated coefficients on the distance grid cells for production and residential fundamentals  $\{a_i, b_i\}$  are always small in magnitude and often statistically insignificant.

In the web appendix, we report the results of a robustness test, in which we assume values of  $\nu = \epsilon\kappa = 0.07$  and  $\epsilon = 6.83$  from our earlier gravity equation analysis, and structurally estimate the remaining agglomeration parameters  $\{\lambda, \delta, \eta, \rho\}$  using our moment conditions for production and residential fundamentals ((30) and (31) respectively). As reported in the web appendix, we find similar estimated values for the strength of agglomeration forces in production and residential choices.

## 7.6 Comparison with Existing Estimates of Agglomeration Economies

As discussed in the introduction, an extensive literature has regressed economic outcomes (such as wages) on the density of economic activity using data across cities or regions. As summarized by Rosenthal and Strange (2004), “doubling city size seems to increase productivity by an amount that ranges from 3-8 percent,” and studies that control for worker sorting find estimated spillovers towards the lower end of this range, as in Combes, Duranton, and Gobillon (2008).<sup>49</sup> Using quasi-experimental evidence, Kline and Moretti (2014) estimate a somewhat higher elasticity of 0.2 for the Tennessee Valley Authority, while Greenstone, Hornbeck, and Moretti (2010) find large productivity spillovers from comparing “winning” and “losing” counties competing for large manufacturing plants. Our estimate of the elasticity of productivity with respect to production externalities ( $\lambda = 0.07$ ) is towards the high end of the 3-8 percent range, but less than the elasticities implied by these other quasi-experimental studies.

In comparing our results to the findings from this existing literature, a number of points must be taken into account. First, the zero-profit condition in production (12) links overall productivity to wages and floor prices. Therefore lower estimates of agglomeration economies using data on wages, for example, could reflect that higher productivity leads to both higher wages and higher floor prices.<sup>50</sup> Second, our estimate of  $\lambda = 0.07$  captures the effect of doubling workplace employment density holding constant travel times.

<sup>49</sup>In a recent meta-analysis of estimates of urban agglomeration economies, Melo, Graham, and Noland (2009) report a mean estimate of 0.058 across 729 estimates from 34 studies, consistent with Rosenthal and Strange (2004).

<sup>50</sup>To further explore this point, we estimate elasticities of floor prices, wages and productivity with respect to distance from the pre-war CBD in 2006, which are -0.20, -0.10 and -0.12 respectively. Therefore some of the higher productivity close to the CBD is indeed reflected in higher floor prices as well as in higher wages. The wage and productivity elasticities weighted by their coefficients in zero-profits (12) add up to the floor price elasticity:  $-((0.8/0.2) \times -0.10) + ((1/0.2) \times -0.12) = -0.20$ .

In reality, a doubling in total city population is typically achieved by a combination of an increase in the density of workplace employment and an expansion in geographical land area, with the accompanying increase in average travel times within the city. Therefore the elasticity of productivity with respect to such a doubling of total city population is less than  $\lambda = 0.07$ , because an increase in average travel times reduces production externalities at a rate determined by the spatial decay parameter  $\delta$ .<sup>51</sup>

Our findings of substantial and highly localized production externalities are also consistent with recent research using within-city data. Using data on the location of advertising agencies in Manhattan, [Arzaghi and Henderson \(2008\)](#) find little evidence of knowledge spillovers beyond 500 meters straight-line distance. To compare straight-line distances to travel times, we computed the mean travel time in 2006 across all bilateral connections in our data that cover a straight-line distance between 450 to 550 meters, which is approximately 9 minutes.<sup>52</sup> After 9 minutes of travel time our estimates suggest production externalities have declined to around 5 percent.

Our findings of residential externalities are consistent with the idea that amenities are endogenous to the surrounding concentration of economic activity, as in [Glaeser, Kolko, and Saiz \(2001\)](#) and [Diamond \(2013\)](#). While higher population density can create negative spillovers, such as air pollution and crime, it can also have positive externalities through the availability of urban amenities. Our estimates of the elasticity of amenities with respect to residential externalities ( $\eta$ ) suggest that the net effect of these opposing forces is positive. Although  $\eta$  captures the direct effect of higher population density on utility through amenities, there are clearly other general equilibrium effects through floor prices, commuting times and wages.

Our findings of large and highly localized residential externalities are consistent with other evidence on spillovers in residential choices. [Rossi-Hansberg, Sarte, and Owens \(2010\)](#) uses data on urban revitalization programs in Richmond, Virginia, and finds that each dollar of home improvement spending generated between \$2 and \$6 in land value by way of externalities in the targeted neighborhoods, but housing externalities fall by approximately one half every 1,000 feet.

## 7.7 Overidentification Checks

In addition to the over identification that we have already reported using commuting data, we now examine the model's predictions for other variables not used in the estimation. In our structural estimation, we use the equilibrium relationships of the model to solve for the adjusted density of development ( $\tilde{\varphi}_i$ ) that equates the supply of floor space to the model's implied demand for floor space. We now compare these predictions of the model to separate data on the ratio of floor space to geographical land area ("GFZ") that is not used in its estimation. We do not expect the relationship between the model's predictions and the data to be perfect.

---

<sup>51</sup>To illustrate the quantitative relevance of this point, we have used the model to estimate the median impact on the productivity of a West Berlin block of spillovers from East Berlin in 1936, which corresponds to 0.0223 log points. In contrast, if one could distribute the workplace employment of East Berlin proportionately to each West Berlin block, this would increase workplace employment in each West Berlin block by a factor of 1.7556, and hence would increase the productivity of each West Berlin block by  $0.0738 \times \ln(1.7556) = 0.0415$  log points.

<sup>52</sup>The standard deviation of travel times in the 450 to 550 meter straight-line distance bin is 3.4 minutes, which illustrates that straight-line distances are an imperfect proxy for actual travel times in cities, particularly over shorter distances.

Our measure of the adjusted density of development from the model ( $\tilde{\varphi}_i$ ) includes other variables that enter the model isomorphically to  $\varphi_i$  and this measure in the model is implicitly quality adjusted. In contrast, our measure of the ratio of floor space to geographical land area in the data is coarse, because it is based on a number of discrete categories (e.g. greater than 4.5), and it does not control for the quality of floor space. Nonetheless, as reported in Table A.15 of the web appendix, we find a strong, statistically significant and approximately log linear relationship between the two variables. For example, the estimated coefficient in 2006 is close to one (0.9610 with Conley standard error 0.0181), with an R-squared of 0.37. Given the caveats noted above, and the fact that this is a univariate regression using cross-sectional micro data, the strength of this empirical relationship provides further support for the model’s predictions.

As an additional external validity test, we examine whether our estimates of adjusted production and residential fundamentals  $\{\tilde{a}_i, \tilde{b}_i\}$  in 2006 are correlated with observable block characteristics that plausibly affect their suitability for production or residence. As reported in Table A.16 of the web appendix, we find that our estimates of residential fundamentals are positively correlated with green areas, proximity to water and listed buildings, and negatively correlated with noise and the level of destruction in the Second World War. We also find a plausible pattern of results for adjusted production fundamentals. Production fundamentals are uncorrelated with the level of noise, are at best weakly correlated with the level of war-time destruction, and are positively correlated with the other observable block characteristics. Therefore our estimates of production and residential fundamentals are related in the expected way to separate data on observable correlates for these variables.

## 7.8 Counterfactuals

In subsection 6.3, we reported the results of counterfactuals for the special case of the model with exogenous location characteristics  $\{\tilde{A}_i, \tilde{B}_i, \tilde{\varphi}_i\}$ , in which case the model has a unique equilibrium. In this section, we report the results of counterfactuals for the estimated model with agglomeration and dispersion forces  $\{\nu, \epsilon, \lambda, \gamma, \eta, \rho\}$ . In the presence of these agglomeration forces, there is the potential for multiple equilibria in the model. We solve for the counterfactual equilibrium using the initial values from the observed equilibrium prior to division or reunification. Therefore we assume the equilibrium selection rule of solving for the closest counterfactual equilibrium to the observed equilibrium prior to division or reunification. Our goal in these counterfactuals is not to determine the unique impact of division or reunification, but rather to examine whether the model with the estimated agglomeration and dispersion forces is capable of generating counterfactual predictions for the impact of division or reunification close to the observed impact.

In each of our counterfactuals, we solve for the counterfactual impact of division or division, and estimate our baseline “difference-in-difference” specification (22) using the counterfactual instead of the actual change in floor prices. In our first counterfactual, we simulate the impact of division on West Berlin, holding adjusted production fundamentals, residential fundamentals and the density of development  $\{\tilde{a}_i, \tilde{b}_i, \tilde{\varphi}_i\}$  constant at their 1936 values. As reported in Column (1) of Table 7, we find counterfactual treatment effects of division close to the observed treatment effects (e.g. -0.839 versus -0.800 for the first distance grid cell). Therefore the model for the estimated values of agglomeration and dispersion forces is able to account

quantitatively for the observed impact of division.

To examine the respective contributions of production and residential externalities, Column (2) simulates the impact of division setting residential externalities to zero ( $\eta = 0$ ), while Column (3) simulates the impact of reunification setting production externalities to zero ( $\lambda = 0$ ). In each case, we find counterfactual treatment effects of division of around three-quarters of the magnitude of the observed treatment effects (e.g. -0.667 and -0.666 versus -0.800 for the first distance grid cell). Therefore both production and residential externalities make substantive contributions to the overall impact of division. Furthermore, their effects are not additive, because the losses of production and residential externalities are correlated with one another and the model is non-linear.

To examine the role of the spatial decay of production and residential externalities, Column (4) simulates the impact of division halving the rates of spatial decay of both production externalities and residential externalities ( $\delta, \rho$ ). In this case, we find slightly smaller estimated treatment effects of division across the six distance grid cells included in the table, because the impact of division now extends further into West Berlin, reducing floor prices for blocks in the excluded category.

In our final two counterfactuals, we examine the impact of reunification. In Column (5), we simulate the reunification of East and West Berlin, holding adjusted production and residential fundamentals for West Berlin constant at their 1986 values, and using the 2006 values of adjusted production and residential fundamentals for East Berlin. As shown in the table, we find counterfactual treatment effects of reunification close to the observed treatment effects (e.g. 0.472 versus 0.398 for the first distance grid cell). Therefore the model for the estimated values of agglomeration and dispersion forces is also able to account quantitatively for the observed impact of reunification.

Finally, in Column (6), we simulate the reunification of East and West Berlin, holding adjusted production and residential fundamentals for West Berlin constant at their 1986 values, and using the 1936 values of adjusted production and residential fundamentals for East Berlin. We now find counterfactual treatment effects of reunification substantially larger than the observed treatment effects (e.g. 0.923 versus 0.398 for the first distance grid cell). This pattern of results is consistent with the idea that a recovery of East Berlin to the relative levels of economic development prior to the Second World War would lead to a further reorientation of economic activity within West Berlin.

## 8 Conclusions

In this paper, we develop a quantitative theoretical model of city structure that incorporates agglomeration and dispersion forces, allows for asymmetries in locational fundamentals, and remains tractable and amenable to empirical analysis. To separate out agglomeration and dispersion forces from heterogeneity in locational fundamentals, we combine the model with the exogenous source of variation in the surrounding concentration of economic activity provided by Berlin's division and reunification.

The model implies a gravity equation for bilateral commuting flows, which is successful in accounting for observed commuting patterns. We find substantial differences in productivity and amenities across

locations within cities that are endogenous to the surrounding concentration of economic activity. While our estimates of the elasticity of productivity with respect to density using within-city data are somewhat higher than those using across-city data, we highlight the importance of taking into account the rapid spatial decay of production externalities when comparing estimates at different levels of spatial aggregation. We also find residential externalities of a comparable magnitude to production externalities.

We show that the special case of the model in which productivity and amenities are exogenous is unable to account quantitatively for the observed treatment effects of division and reunification. In contrast, for the estimated values of agglomeration forces, the model is successful in accounting for these observed treatment effects. Although we use the natural experiment of Berlin to estimate the model's parameters, our quantitative framework can be applied in a number of other settings.

Observations	144	122	122	122
R-squared	0.8261	0.9059	-	-

Note: Gravity equation estimates based on representative micro survey data on commuting for Greater Berlin for 2008. Observations are bilateral pairs of 12 workplace and residence districts (post 2001 Bezirke boundaries). Travel time is measured in minutes. Fixed effects are workplace district fixed effects and residence district fixed effects. The specifications labelled more than 10 commuters restrict attention to bilateral pairs with 10 or more commuters. Poisson PML is Poisson Pseudo Maximum Likelihood estimator. Gamma PML is Gamma Pseudo Maximum Likelihood Estimator. Standard errors in parentheses are heteroscedasticity robust. \* significant at 10%; \*\* significant at 5%; \*\*\* significant at 1%.

Note: Columns (1)-(4) based on calibrating the model for  $\nu=\epsilon\kappa=0.07$  and  $\epsilon=6.83$  from the gravity equation estimation. Columns (5)-(6) report counterfactuals for these parameter values. A denotes adjusted overall productivity. B denotes adjusted overall amenities. QC denotes counterfactual floor prices (simulating the effect of division on West Berlin). Column (5) simulates division holding A and B constant at their 1936 values. Column (6) simulates reunification holding A and B for West Berlin constant at their 1986 values and using 1936 values of A and B for East Berlin. CBD1-CBD6 are six 500m distance grid cells for distance from the pre-war CBD. Heteroscedasticity and Autocorrelation Consistent (HAC) standard errors in parentheses (Conley 1999). \* significant at 10%; \*\* significant at 5%; \*\*\* significant at 1%.

Table 4: Floor Prices, Productivity and Amenities

	(1) Division Efficient GMM	(2) Reunification Efficient GMM	(3) Division and Reunification Efficient GMM
Commuting Travel Time Elasticity ( $\kappa\epsilon$ )	0.0951*** (0.0016)	0.1011*** (0.0016)	0.0987*** (0.0016)

Productivity Elasticity ( $\lambda$ )	0.0738*** (0.0056)	0.0449*** (0.0071)	0.0657*** (0.0048)
Productivity Decay ( $\delta$ )	0.3576*** (0.0945)	0.8896*** (0.3339)	0.3594*** (0.0724)
Residential Elasticity ( $\eta$ )	0.1441*** (0.0080)	0.0740*** (0.0287)	0.1444*** (0.0073)
Residential Decay ( $\rho$ )	0.8872*** (0.2774)	0.5532 (0.3699)	0.7376*** (0.1622)

Note: Generalized Method of Moments (GMM) estimates. Heteroscedasticity and Autocorrelation Consistent (HAC) standard errors in parentheses (Conley 1999). \* significant at 10%; \*\* significant at 5%; \*\*\* significant at 1%.

Table 5: Generalized Method of Moments (GMM) Estimation Results

	(1) Production Externalities ( $1 \times e^{-\delta t}$ )	(2) Residential Externalities ( $1 \times e^{-\rho t}$ )	(3) Utility after Commuting ( $1 \times e^{-\kappa t}$ )
0 minutes	1.000	1.000	1.000
1 minute	0.698	0.478	0.987
2 minutes	0.487	0.229	0.975
3 minutes	0.340	0.109	0.962
5 minutes	0.166	0.025	0.938
7 minutes	0.081	0.006	0.914
10 minutes	0.027	0.001	0.880
15 minutes	0.005	0.000	0.825
20 minutes	0.001	0.000	0.774
30 minutes	0.000	0.000	0.681

Note: Proportional reduction in production and residential externalities with travel time and proportional reduction in utility from commuting with travel time. Travel time is measured in minutes. Results are based on the pooled efficient GMM parameter estimates:  $\delta=0.3594$ ,  $\rho=0.7376$ ,  $\kappa=0.0128$ .

Note: This table is based on the parameter estimates pooling division and reunification from Table 5. QC denotes counterfactual floor prices. Column (1) simulates division using our estimates of production and residential externalities and 1936 fundamentals. Column (2) simulates division using our estimates of production externalities and 1936 fundamentals but setting residential externalities to zero. Column (3) simulates division using our estimates of residential externalities and 1936 fundamentals but setting production externalities to zero. Column (4) simulates division using our estimates of production and residential externalities and 1936 fundamentals but halving their rates of spatial decay with travel time. Column (5) simulates reunification using our estimates of production and residential externalities, 1986 fundamentals for West Berlin, and 2006 fundamentals for East Berlin. Column (6) simulates reunification using our estimates of production and residential externalities, 1986 fundamentals for West Berlin and 1936 fundamentals for East Berlin. CBD1-CBD6 are six 500m distance grid cells for distance from the pre-war CBD. Heteroscedasticity and Autocorrelation Consistent (HAC) standard errors in parentheses (Conley 1999). \* significant at 10%; \*\* significant at 5%; \*\*\* significant at 1%.

Table 7: Counterfactuals
